The fraction of HO<sub>2</sub><sup>-</sup> production during oxygen reduction as estimated from RRDE voltammograms ( $X_{\text{H}_2\text{O}_2}$ )<sup>3</sup> for the Co-OEP/La<sub>0.6</sub>Sr<sub>0.4</sub>Mn<sub>0.6</sub>Fe<sub>0.4</sub>O<sub>3</sub>/C was much lower (ca. 0.15) than those for Co-OEP/C (ca. 0.7), indicating enhancement of quasi-four-electron reduction of O<sub>2</sub> by combining Co-OEP and La<sub>0.6</sub>Sr<sub>0.4</sub>Mn<sub>0.6</sub>Fe<sub>0.4</sub>O<sub>3</sub>. The reason for high ORR activity of the Co-OEP/La<sub>0.6</sub>Sr<sub>0.4</sub>Mn<sub>0.6</sub>Fe<sub>0.4</sub>O<sub>3</sub>/C catalyst is that HO<sub>2</sub><sup>-</sup> which produced by Co-OEP is reduced to OH<sup>-</sup> by perovskite-type La<sub>0.6</sub>Sr<sub>0.4</sub>Mn<sub>0.6</sub>Fe<sub>0.4</sub>O<sub>3</sub>.

To compare the ORR performances of porphyrin/perovskite/carbon with different compositions of perovskite oxide or structures of porphyrin complex, we prepared catalysts with several types of perovskite and porphyrin complex. ORR activity was also enhanced by Co-OEP-modification of other types of La-based perovskite-type oxide. Porphyrin complex with two different structures (cobalt tetraphenylporphyrin (Co-TPP), iron octaethylporphyrin (Fe-OEP)) were added to the La<sub>0.6</sub>Sr<sub>0.4</sub>Mn<sub>0.6</sub>Fe<sub>0.4</sub>O<sub>3</sub>/C. The onset potential of the Co-TPP-modified catalyst and Fe-OEP-modified catalyst did not shift to the positive direction, because of the lower activity compared to Co-OEP.

# The Degradation of Oxygen Reduction Activity at Stepped Platinum Surfaces in Acidic Media

Yan-Xia Chen,\* YongLi Zheng, Zhengda He and Jie Wei

*Hefei National Laboratory for Physical Sciences at Microscale, Department of Chemical Physics,  
University of Science and Technology of China, Hefei, 230026, China  
yachen@ustc.edu.cn*

Understanding the structure-activity relationship of Pt group metals toward oxygen reduction reaction (ORR) is one of the most extensively investigated topics in the past 60 years, because of its great significance in both fundamental studies and in guiding the rational design of improved ORR catalysts for low temperature fuel cells. From Systematic studies by Feliu's group, it is found that in acid media the ORR activity at Pt[n(111)×(111)] stepped surfaces decreases with the increase in the terrace width, i.e., Pt(331)>Pt(332)>Pt(221)>Pt(111). They found that the ORR is a complex process affected by many different factors and neither surface charge nor oxygen-containing species coverage alone are a determining factor of the electrode activity. Instead, adlayer structures and the relation between adsorbed water, H<sub>2</sub>O<sub>ads</sub>, water dissociation products, OH<sub>ads</sub> or O<sub>ads</sub>, and PtO oxide species coverage affect the whole energetics of the adsorption processes and may determine the surface reactivity.<sup>1</sup> Beside the information on the structure activity relationship, long term stability is also a very important factor to guide the design of practical ORR catalysts.

In order to have a deeper understanding of structure-activity relationship and checking the long term stability of Pt[n(111)×(111)] vicinal faces toward ORR, conventional electrochemical studies using hanging meniscus rotating disk electrode configuration and DFT calculation have been carried out. We find that i) in the first positive-going potential scan in 0.1 M HClO<sub>4</sub>, ORR activity decreases with the order of Pt(331)>Pt(332)>Pt(111), confirming well the data reported by Feliu's group; ii) there is a decrease of ORR activity with decrease in potential scan rate when keeping upper potential limit (E<sub>h</sub>) at 1.0 V<sub>RHE</sub> and electrode rotation speed constant, or with increase in electrode rotation speed while keeping constant scan rate or with time in chronoamperometric transients at constant potentials; iii) Under otherwise identical condition, the decay of ORR current increases in the order of Pt(111)<Pt(331)>Pt(332). All these phenomena suggest poisoning of Pt[n(111)×(111)] during ORR, and the extent for the poisoning decrease in the order of Pt(332)>Pt(331)>Pt(111). The trends in ORR activity and extent of degradation can be well explained by the difference in the binding strength of O-atoms at step and terrace sites at Pt(hkl) surfaces, as supported by DFT calculation. Present study indicate that the activity trends derived from the polarization curves recorded in the first positive-going potential scan, as usually used to evaluate the catalysts' ORR activity, cannot be simply taken as guideline for rational design of improved catalysts for ORR, since the active sites may be poisoned soon during ORR.

Symposium 4: Advances in Fuel Cells from Materials to Systems

Novel sulfonated co-poly (ether sulfone)s (S4Ph-x-PS) based on a new aromatic diol containing four phenyl groups were synthesized and characterized by NMR analysis and titration. The sulfonated co-poly (ether sulfone)s had good proton conductivity in the range of 0.004 to 0.110 S/cm. Single H<sub>2</sub>/O<sub>2</sub> fuel cells based on S4Ph-40-PS loaded with 0.25 mg/cm<sup>2</sup> catalyst (Pt) exhibited the maximum power density of 466.9 mW/cm<sup>2</sup>, which was closed to that of Nafion 212 (533.5 mW/cm<sup>2</sup>) at 80 °C with humidity at 80% RH. While in low relative humidity (53%), fuel cells based on S4Ph-35-PS showed higher peak power density (234.9 mW/cm<sup>2</sup>) than that of Nafion.

Scheme 1. Synthesis route of S4Ph-x-PS copolymers.

Table 1. Peak power density of S4Ph-35-PS and Nafion 212 at 80 °C with various relative humidity.

Relative humidity (%)	S4Ph-35-PS (mW/cm <sup>2</sup> )	Nafion 212 (mW/cm <sup>2</sup> )
53%	234.9	214.0
66%	289.1	344.7
80%	445.1	533.5
100%	372.9	847.4

# IL-FE-SEM Study for Ambience Dependence of Degradation of Pt/C Catalyst

Misako Ikeyama, Taro Kinumoto, Sawaka Kitayama, Miki Matsuoka,  
Tomoki Tsumura and Masahiro Toyoda

Dept. of Appl. Chem., Graduate School of Eng., Oita Univ., 700 Dannoharu, Oita, 870-1192, JAPAN  
kinumoto@oita-u.ac.jp

The carbon black-supported Pt nanoparticle catalyst (Pt/C) is generally employed as the cathode catalyst of proton exchange membrane fuel cells (PEMFCs); unfortunately, it deteriorates with loss of the electrochemical surface area (ECSA). There are several degradation processes that have been qualitatively considered to be responsible for the loss of ECSA [1]. And hence, technology that can be used to continuously monitor the degradation of specific Pt particles in Pt/C is important to further quantitatively understand the degradation process. We have carried out the identical location field emission scanning electron microscopy (IL-FE-SEM) for semi-quantitatively analysis for the degradation mechanism during accelerated degradation test (ADT) according to FCCJ [2]. In this presentation, the effect of atmosphere on the degradation of Pt nanoparticles is reported.

Pt/C catalyst (TEC10E50E, Tanaka Kikinzoku Kogyo, Pt weight = 46.7 wt%) was dispersed on a glassy carbon disk, and then Nafion thin film was formed on the catalyst (calculated thickness = 80 nm), which was employed as the test electrode. FE-SEM observation of Pt/C catalyst was carried out and the observation point was defined for IL-FE-SEM. After that, the test electrode was transferred to a glass half-electrochemical cell filled with 0.1 mol dm<sup>-3</sup> HClO<sub>4</sub> aqueous solution. The potential pulse test (0.6 V - 1.0 V, pulse time = 3 s) was carried out as ADT under N<sub>2</sub> and O<sub>2</sub> atmosphere. IL-FE-SEM observation and cyclic voltammetry measurements were carried out after an arbitrary test period.

Figure 1 shows typical IL-FE-SEM images under O<sub>2</sub> atmosphere. The typical morphological changes were observed for Pt particles such as shrinkage and growth of the particles, disappearance, migration, coalescence, transformation, precipitation on carbon support. Those phenomena were also observed under N<sub>2</sub> atmosphere.

Figure 2 shows the frequencies for degradation processes of Pt particles based on IL-FE-SEM results. Closed and open plots are the results under N<sub>2</sub> and O<sub>2</sub> atmosphere, respectively. The frequency for summation of shrinkage and disappearance are shown as square plots and reached the maximum of ca. 20% for both atmospheres. Growth of the particle was also observed and the frequency (circle plots) under O<sub>2</sub> atmosphere was slightly higher than that under N<sub>2</sub> atmosphere after the 10,000 pulses. The frequency of coalescence (triangular plots) under O<sub>2</sub> atmosphere was clearly higher than that under N<sub>2</sub> atmosphere during the durability test. On the other hand, the frequencies of precipitation (inverted triangle plots) were slightly higher for N<sub>2</sub> atmosphere. Thus, degradation of Pt/C depends on the atmosphere and more details will be mentioned in the presentation.

# **Fabrication of Anode Microporous Layer with Carbon Nanotubes and its Effect on Proton Exchange Membrane Fuel Cell Performance**

Sheng-Wei Huang, Min-Hsing Chang

*Department of Mechanical Engineering, Tatung University*

*Taipei, 104, Taiwan*

*mhchang@ttu.edu.tw*

Proton exchange membrane fuel cells (PEMFC) have received much attention in the past decades as a clean power source for many potential applications like automotive or stationary power plants. However, its performance still needs improvement in order to meet the requirement of fast response in the power delivery system. One of the major problems restricting the cell performance is the water management within the membrane electrode assembly (MEA). The amount of liquid water flux from anode to cathode induced by the electroosmosis phenomenon and the effect of back-diffusion due to the condensation of water vapor at cathode catalyst layer (CL) are both typically important factors which may affect the water balance within the MEA profoundly. The water management performance depends heavily on the gas diffusion layer (GDL) which is a critical component of MEA. In general, the GDL is sandwiched between the CL and the gas flow channel and a dual-layer structure which consists of a macroporous substrate made by carbon paper or carbon cloth and a thin carbon layer coated on its surface. The thin carbon layer is named microporous layer (MPL) which is adjacent to the CL on both sides of MEA and generally contains carbon black powder and hydrophobic agent like polytetrafluoroethylene (PTFE) for the management of two-phase water flow. Accordingly, the GDL properties are quite important in water management and it becomes a challenge to achieve maximum cell performance by improving the GDL properties. Numerous studies have been published in the literature to investigate the effects of GDL and MPL on PEMFC performance. Most of them focused on the effects of cathode GDL or MPL. The study for the influence of anode MPL is relatively limited and it still needs to be explored further. The purpose of this research is to measure the variation of cell performance for a PEMFC using multiwall carbon nanotubes (CNTs) as the composition of MPL material in the anode GDL. The CNT loading and the PTFE content in the anode MPL are adjusted and their effects on the cell performance are explored. Accordingly, the optimal composition of anode MPL including CNT loading and PTFE content could be determined. The techniques of electrochemical impedance spectroscopy and cyclic voltammetry have been used in the experiments. The results show that the employment of multiwall CNT as anode MPL material indeed may improve the cell performance. The optimal composition of anode MPL is found to be 1.0 mg/cm<sup>2</sup> of CNT loading with 20 wt% of PTFE content. Results provide a full understanding for the role of CNT in the fabrication of MPL for a PEMFC system.

# Synthesis of Pt Nanoparticles using Microbubble-assisted Low-Voltage Low Frequency Solution Plasma Processing

## 1. Introduction

A solution plasma processing method at a low voltage and a low frequency, abbreviated as SPP-LVLF, is promising for the synthesis of Pt nanoparticles for polymer electrolyte fuel cells because of a simple and easy method and low environmental load. However, one of major problems with the method is that the size of Pt particles is too large (5 - 20 nm) to use as catalysts. In this report, we show the synthesis of 3.3 nm Pt particles by a microbubble-assisted SPP-LVLF (abbreviated as MBSP).

## 2. Experimental

Microbubbles were generated in a 0.86 – 2.58 mM KNO<sub>3</sub> aqueous solution heated to 45°C using a microbubble generator (OKE-MATRIX-MB01, OK engineering Ltd.). The solution was fed to a flow cell at a 24 mL min<sup>-1</sup>, where a tungsten wire (1.0 mmφ, Nilaco Corp.) and one or two Pt wire(0.5 mmφ, Nilaco Corp.) were inserted with 0.2 mm gap. Pt nanoparticles were produced by applying half-wave rectified waves (440 V) with a power transformer (SD41-02KB, Toyozumi Dengenkiki Corp.) between the two electrodes for 4 to 10 min. The solution was filtered with a membrane filter (Millipore 0.1 μm), then Vulcan XC-72R (Cabot) was suspended to the solution with stirring for 24 h. After the suspension was concentrated by a rotary evaporator, the Pt nanoparticles mixed with XC-72R (Pt/XC72) were washed by decantation with Milli-Q water, and were allowed to dry under vacuum. The Pt/XC72 were characterized by XRD, FE-SEM, and TG.

A 2.0 mg of the Pt/XC72 catalysts was suspended by shaking with zirconia balls in 1 mL of 0.1 wt% Nafion-MeOH by ultrasonication. A 10 μL of the suspension was cast onto a glassy-carbon disk (6 mm φ, 0.283 cm<sup>2</sup>) – Pt ring electrode (Nikko Keisoku) and dried for 1 h under N<sub>2</sub> atmosphere. Electrochemical properties were investigated by the rotating ring-disk electrode (RRDE) method with the modified electrode as a working, a RHE as a reference, and a gold wire as a counter electrodes in 0.1 M HClO<sub>4</sub>. Finally, an accelerated durability test (ADT) was performed by the FCCJ cycle test method with a triangular wave (1.0 to 1.5 V).

## 3. Results and Discussion

Table 1 shows the number of light emissions and the particle sizes of Pt prepared by the MBSP method at various KNO<sub>3</sub> concentrations. The number of plasma emission tended to increase with the concentration of KNO<sub>3</sub>, which is due to the increase in the ionic conductivity. The size of Pt nanoparticles was severely affected by the concentration of KNO<sub>3</sub>, and the Pt nanoparticles synthesized in 2.06 mM KNO<sub>3</sub> was the smallest in the condition.

Fig. 1 shows the dependence of oxygen reduction current normalized by initial electrochemical surface area at 0.95 V on ADT time. The ORR current of the catalysts prepared by the MBSP was higher than that of Pt/XC72 (E-TEK).

Table 1 Result of Pt nanoparticle synthesis by the microbubble-assisted LVLF-SP method at various KNO<sub>3</sub> concentrations.

Sample No.	[KNO <sub>3</sub> ] / mM	Number of light emissions / min <sup>-1</sup>	Particle size of Pt / nm <sup>1)</sup>

Symposium 4: Advances in Fuel Cells from Materials to Systems

The most widely used PBI for HT-PEMFC applications is poly-2,2'-(*m*-phenylene)-5,5'-bibenzimidazole (*m*-PBI), which possesses several excellent qualities such as thermal stability, mechanical strength, acid-attracting ability and proton conductivity. Numerous PBIs have been synthesized and investigated for such applications. However, PBIs based on new tetraamines are relatively rare. In this study, we report three polybenzimidazoles, **P1~P3**, derived from new tetraamines. **P1~P3** exhibited good thermal stability, oxidative stability, mechanical properties as well as solubility in common aprotic polar solvents. In addition, the phosphoric acid-doped **P1~P3** membranes exhibited high proton conductivity in the range of  $3.99 \times 10^{-2} \sim 5.34 \times 10^{-2} \text{ S cm}^{-1}$ . They also demonstrated high performance on single cell test, with peak power density of 478~636  $\text{mW/cm}^2$  at 160 °C with acid uptakes of 199~241 %.

**Figure 1.** Polarization curves of PBIs.

# Plasmonic Induced Inhibition and Enhancement of the Electrocatalytic Activity for Ethanol Oxidation on Pd/Au Hetero-Nanoraspberries

Xiaoqiang Cui

*Department of Materials Science, Key Laboratory of Automobile Materials of MOE and State Key Laboratory of Superhard Materials, Jilin University, Changchun, 130012, People's Republic of China  
xqcui@jlu.edu.cn*

Plasmonic modulating the catalytic performances of metallic nanostructures shows great potential in developing novel materials for catalysis. Besides the challenges of devising new catalysts with high activity while keeping controllable plasmonic property, the mechanisms beneath the enhancement of the activity by surface plasmon resonance (SPR) is still under exploring. We designed and implemented a Pd-Au bimetallic heterostructure that carry the well-defined surface plasmonic resonance property of Au NPs that used as the core to tune the electrocatalytic performance on the hetero-nanostructures' surface. With excellent morphology control, we provide chances of tuning their catalytic properties with respect to the Pd antenniform nanoislands and the incorporated Au cores. We also demonstrate that, with visible-light irradiation, the electron resonated with the photons could transfer to the Pd nanopetals from Au, resulting in the enhancement of electrocatalytic performance on Au and inhibition on Pd. Besides, the anti-poisoning property and stability of as-prepared samples can also be enhanced by the visible-light-irradiation.

h-shiroishi@tokyo-ct.ac.jp

## 1. Introduction

In the case of evaluating the activity of a catalyst with the rotating ring disk electrode (RRDE) method, casting an aliquot of the catalyst suspension, which is mostly prepared with ultrasonic wave or planetary ball mill, on a glassy carbon (GC) electrode is the general method. However the dispersing quality of the catalyst on the GC electrode depends on kinds of catalysts and solvent in the suspension<sup>1, 2)</sup>. In this research, we have investigated the dispersiveness of the multiwall carbon nanotube-supported Pt catalyst (Pt/MWCNT) on the GC electrode prepared with four devices: an ultrasonic bath, a planetary ball mill, a stirrer, and a shaker. The evaluation of the dispersiveness has been performed by microscope observation and electrocatalytic measurements for oxygen reduction and ammonia oxidation reaction.

## 2. Experimental

3.6 wt% Pt/MWCNT ( $5.57 \pm 0.11$  nm) was synthesized with a microwave-polyol method. 2 mg of Pt/MWCNT was suspended in 1 mL of 0.1 wt% Nafion-MeOH by four dispersion methods: 1) ultrasonic method (sample name: US-ultrasonic exposure time), 2) stirring method (sample name: ST-rotating speed-stirring time), 3) planetary ball mill method (sample name: PB-rotating speed-rotating time-the number of zirconia balls) and 4) shaking method with adding zirconia balls (SH-rotating speed-shaking time-number of zirconia balls). 10  $\mu$ L of each suspension was cast on a GC electrode and dried in air for 1 h. The dispersiveness of each electrode was observed with digital microscope (MSP-3080, PANRICO). In electrochemical measurements, ECSA was estimated with conducting CO-stripping in 0.1 M HClO<sub>4</sub> using RHE as a reference electrode and Au wire as a counter electrode. The activity of ammonia oxidation was evaluated in 0.1 M NH<sub>3</sub>-0.1 M KOH under N<sub>2</sub> atmosphere after the activity of oxygen reduction reaction was performed in 0.1 M KOH under N<sub>2</sub> or O<sub>2</sub> atmosphere by the RRDE method.

## 3. Results and Discussion

Fig. 1 shows the microscopic images of the GC electrode surface prepared by various dispersion methods. The dark area of the images is GC electrode surface, whereas the catalyst particles exist in the bright diffuse area. The catalyst particles prepared by ultrasonic (Fig. 1(a)) or planetary ball mill (Fig. 1(d)) methods was uniformly dispersed on the GC electrode surface compared to those by stirring (Fig. 1(b)) or shaking (Fig. 1(c)) method by which the catalyst particles often aggregated at the center not to reach the circumference of the GC electrode surface. The amount of H<sub>2</sub>O<sub>2</sub> generated by electrochemical oxygen reduction reaction with the electrode prepared by ultrasonic or planetary ball mill method tended to be larger than those by stirring or shaking method, indicating that the quantity of H<sub>2</sub>O<sub>2</sub> cannot be precisely determined without uniform dispersion of the catalyst on the GC electrode. The electrode prepared by stirring or shaking is not good at ammonia oxidation. The aggregated catalyst would affect the adsorption of NH<sub>3</sub> on the catalyst surface by generating N<sub>2</sub> gas. From these results, the difference in the condition of the catalyst cast on the GC electrode is suggested to depend on the dispersion method, consequently, the optimization of the dispersion method is indispensable for the precise evaluation of the catalyst activity.

An anode-supported honeycomb solid oxide fuel cell can achieve high volumetric power density and improve thermo-mechanical durability at high temperatures. We have so far fabricated the honeycomb cell with a cathode layer of LSM and an electrolyte layer of 8YSZ on a porous anode honeycomb substrate of Ni/8YSZ. The anode-supported honeycomb cell exhibited promising volumetric power densities[1]. Effect of flow channel configurations on the cell performance was investigated in terms of the hydrogen partial pressure distributions in the cell under operation as well[1]. In this study, we compare the differences of measured current-voltage and current-power density curves between the honeycomb cells having porous substrate thicknesses of 0.5 mm and 1.0 mm shown in Fig. 1 under different hydrogen flow rates. Thinner substrate gives better performance for smaller fuel flow rates. The effect of hydrogen partial pressure distributions associated with the anode-substrate thickness on the cell performance is numerically clarified with finite element modeling.

Fig. 1 Cross-sectional pictures of the honeycomb cells with anode substrate thicknesses of (a) 0.5 mm and (b) 1.0 mm. (c) A and C represent anode and cathode flow channels, respectively.

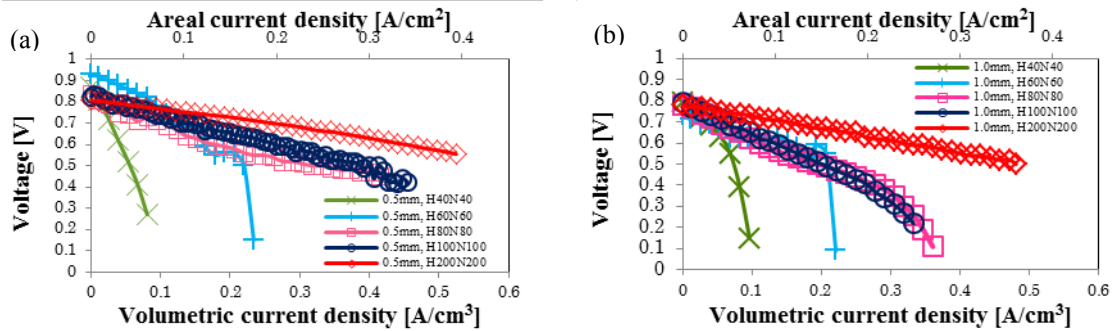

Fig. 2 Current-voltage characteristics for the honeycomb cell with anode thicknesses of (a) 0.5 mm and (b) 1.0 mm at 850 °C, H<sub>2</sub>/N<sub>2</sub>: 40/40, 60/60, 80/80, 100/100, and 200/200 cm<sup>3</sup>/min, air: 400 cm<sup>3</sup>/min in total.

Solid oxide fuel cells (SOFCs) are electrochemical power-generation systems characterized by high conversion efficiency, low environmental impact, excellent fuel flexibility, and ability to use non-precious-metal catalysts. Typical SOFCs, which operate at a temperature of approximately 1000 °C, are based on oxygen-ion-conducting electrolytes. Recently, SOFCs based on proton-conducting electrolytes (H<sup>+</sup>-SOFC) have attracted considerable attention due to their relatively low operation temperature (400-800 °C) that facilitates the selection of the sealing and interconnection materials, control of the interactions between the electrode/electrolyte, and lowering of the thermal expansion mismatch between the cell components. Moreover, lowering the operation temperature also reduces the capital costs and prolongs cell lifetime. The key issue for H<sup>+</sup>-SOFC development is finding a suitable proton-conducting electrolyte material.

In this study, Sr(Ce<sub>0.6</sub>Zr<sub>0.4</sub>)<sub>0.85</sub>In<sub>0.15-x</sub>Y<sub>x</sub>O<sub>3-δ</sub> proton-conducting oxides are prepared by citrate-EDTA complexing method. The basic properties and electrochemical properties of Sr(Ce<sub>0.6</sub>Zr<sub>0.4</sub>)O<sub>3-δ</sub> co-doped with indium and yttrium are investigated. Its micro-structure patterns and sintered behavior are characterized by X-ray diffraction (XRD), field-emission scanning electron microscope (FE-SEM) and thermal mechanical analyzer (TMA). The XRD patterns and SEM images shows that the Sr(Ce<sub>0.6</sub>Zr<sub>0.4</sub>)<sub>0.85</sub>In<sub>0.15-x</sub>Y<sub>x</sub>O<sub>3-δ</sub> powder was synthesized with Zr<sub>0.5</sub>Ce<sub>0.5</sub>O<sub>2</sub> impurity phase. The relative sintering density of all Sr(Ce<sub>0.6</sub>Zr<sub>0.4</sub>)<sub>0.85</sub>In<sub>0.15-x</sub>Y<sub>x</sub>O<sub>3-δ</sub> is higher than 99%. The conductivity of the sintered Sr(Ce<sub>0.6</sub>Zr<sub>0.4</sub>)<sub>1-x</sub>Y<sub>x</sub>O<sub>3-δ</sub> disk measured at various temperatures in air using the 2-probe DC method. The conductivity of Sr(Ce<sub>0.6</sub>Zr<sub>0.4</sub>)<sub>0.85</sub>Y<sub>0.15</sub>O<sub>3-δ</sub> apparently increased as the temperature above 600 °C. The conductivity of Sr(Ce<sub>0.6</sub>Zr<sub>0.4</sub>)<sub>0.85</sub>Y<sub>0.15</sub>O<sub>3-δ</sub> is 0.000984 S/cm and 0.01467 S/cm at 600°C and 900°C, respectively. The phase stability of Sr(Ce<sub>0.6</sub>Zr<sub>0.4</sub>)<sub>0.85</sub>In<sub>0.15-x</sub>Y<sub>x</sub>O<sub>3-δ</sub> was investigated in 80 °C water for 60h, no second phase was observed.

# Crosslink-free highly sulfonated multi-block poly(arylene ether sulfone) multi-block membranes for PEMFC

Sojeong Lee and Byungchan Bae\*

Fuel Cell Laboratory, Korea Institute of Energy Research (KIER), 152, Gajeong, Yuseong, Daejeon, 305-343, Korea

E-mail: bcbae@kier.re.kr

Perfluorinated sulfonic acid (PFSA) membranes for fuel cell, such as Nafion (DuPont) and Aquivion (Solvay), are commonly used because of their high ionic conductivities and excellent mechanical properties; however, their high manufacturing cost and low thermal stability are major drawbacks. Heat-resistant and inexpensive aromatic hydrocarbon-based membranes seem to be successful potential alternatives to PFSA membranes.[1,2] More recently, the introduction of highly sulfonated hydrophilic blocks (almost one sulfonic acid per benzene ring) resulted in comparable proton conductivity to those of PFSA membranes. However, most of these compounds contained crosslinks because decafluorobiphenyl or hexa-fluorobenzene chain-extenders were used. Crosslinking during polymerization resulted in undesirable low solubility and defects.

In this study, we succeeded in synthesizing high-molecular weight SPAES multi-block polymers free from perfluorinated end-groups and crosslinking defects.[3] A block sulfonated poly (arylene ether sulfone) copolymer (SPAES) was synthesized through nucleophilic aromatic substitution between hydrophilic and hydrophobic oligomeric precursors. By increasing the purity of the oligomers and determining the optimum solvent for each segment, polymerization successfully generated high-molecular weight polymers. Highly sulfonated hydrophilic block polymers were designed and the resultant block membrane showed very high proton conductivity even under low RH as shown in Figure 1. (0.48 and 0.035 S cm<sup>-1</sup> at 90% and 40% RH, respectively, at 80°C) These values were higher than that of a commercial PFSA membrane. The presence of well-formed proton pathways from the hydrophilic clusters was confirmed by TEM; these explain the very high proton conductivity even under low RH conditions. The fuel-cell performance reached 250 mA cm<sup>-2</sup> at 0.7 V at 120°C, 40% RH, and atmospheric conditions.

Figure 1. RH dependence of Proton conductivity of block SPAES, Aquivion, and Nafion membranes at 80°C.

Alternative hydrocarbon-based (HC) membranes for proton exchange membrane fuel cell (PEMFC) application have been developed to overcome high cost of perfluorosulfonic acid membrane (Nafion). However, commercialization of HC membranes has been impeded due to its poor chemical (oxidative) stability during fuel cell operation. In this study, we prepared HC composite membranes with cerium ions and its investigated possibility as radical quencher was investigated for suppressing oxidative decomposition of HC membranes.

Composite polymer electrolytes were prepared by immersion and mixing method using sulfonated poly(arylene ether sulfone) (SPES, 50% DS) along with different content of cerium ion.<sup>[1]</sup> FE-SEM mapping imaging, ICP-AES and <sup>1</sup>H-NMR confirmed successful exchange of sulfonic acid group with metal ions. Also, influence of the additives on water uptake, IEC and proton conductivity was examined.

The effects of cerium ion on HC membrane oxidative stability were investigated through hydrogen peroxide exposure experiment (ex-situ) and accelerated OCV durability test (in-situ). According to the results durability test as shown in Figure 1, the oxidative degradation of HC-membranes was suppressed by quenching effect of found to be decreased with cerium ions. Long-term stability of more than 2000 h was achieved with the composite membrane whereas corresponding pristine SPES membrane showed attained only 700 h (Fig. 1). We will also compare two different methods, mixing and impregnation, for the preparation of composite membranes. The obtained results indicate that the cerium ions functioned as radical quencher to suppress oxidative degradation in the membranes. Especially, the composite membrane made by immersion method was more stable than that made by mixing method.

This study has suggested the important alternative to improve the electrolyte membrane durability for fuel cells.<sup>[1]</sup>

# Improving the Electrocatalytic Activity of Binary Alloy $\text{Cu}_x\text{Pd}_y$ for Methanol Oxidation Reaction by Tailoring Chemical Composition

Xuan Zhang\*, Jia-Wei Zhang, Bei Zhang

College of Chemistry, Chemical Engineering & Biotechnology, Donghua University  
Shanghai 201620, China.

e-mail address: xzhang@dhu.edu.cn

The promising potential in providing future sustainable and clean power source has inspired enormous interest on fuel cells during decades, especially on direct methanol fuel cells (DMFC). Pt- and Pd-based materials are the most popular anode electrocatalysts in DMFC for methanol oxidation reaction (MOR) [1]. However, the commercial mass production of noble Pt- and Pd-based catalysts for DMFC are strongly limited by their high cost, poor durability and low resistance to CO poisoning. Therefore, reducing the cost and improving the performance of electrocatalysts, are two crucial problems blocking a practical application. Alloying noble metal with less expensive metals (Cu, Fe, etc.) has been recognized to be an efficient approach, and it is also known that the composition ratio of alloy is very important in tailoring the catalytic activity [2]. As our continuous study on Pt-based electrocatalysts for both MOR and biosensor [3-6], here we will present research results on improving the activity of binary alloy  $\text{Cu}_x\text{Pd}_y$  electrocatalyst for MOR by tailoring its chemical composition. It has been found that the activity is strongly dependent on chemical composition of alloy (Fig. 1). The preparation, characterization, performance, and enhancement mechanism will be discussed in detail.

Calcium-doped and nickel-doped yttrium chromate (YCCN) are very promising materials with regard to application as conductive coatings for ferritic stainless steels in interconnects – structural elements in intermediate-temperature solid oxide fuel cells (IT-SOFCs). They are characterized by high physicochemical stability and adequate electrical conductivity in the operating temperatures of IT-SOFCs. The synthesis of  $Y_{0.8}Ca_{0.2}Cr_{1-x}Ni_xO_3$  powders with  $x=0, 0.15$ , and  $0.3$  was carried out using the sol-gel method, with EDTA and glycine as chelating agents. Based on the results of thermal analysis (TG/DTA) – Fig.1, phase composition (XRD) – Fig. 2, and morphological observations (SEM) of the gel precursors heated over the range of 800-1200°C, the optimal calcination parameters were found, allowing powders with the desired phase constitution and fine-grain structure to be obtained.

**Fig. 1.** DTA/TG thermal curves recorded for  $Y_{0.8}Ca_{0.2}Cr_{0.85}Ni_{0.15}O_3$  precursor gels.

The XRD analysis indicated that a pure orthorhombic perovskite phase was obtained only for the glycine nitrate method. Perovskites obtained using the EDTA chelating agent were characterized by multi-phase structure, with the predominant phase exhibiting a similar structure to that of  $YCrO_3$ .

**Fig. 2.** XRD patterns obtained for  $Y_{0.8}Ca_{0.2}Cr_{0.85}Ni_{0.15}O_3$  powders.

After calcination, milling and compacting, the powders were sintered in the range of 1400-1700°C, and a number of dense, polycrystalline sinters were obtained. The sample with the best properties and an average relative density of 96.6% was obtained for the samples sintered for 1 hr in air at 1600°C. The influence of the composition of  $Y_{0.8}Ca_{0.2}Cr_{1-x}Ni_xO_3$  sinters on their physicochemical properties is analyzed based on the results of XRD, SEM-EDS and electrical conductivity measurements, with possible applications as conductive coatings considered to be the main criteria.

Solid oxide fuel cells (SOFCs) are highly promising devices that might become efficient sources of electrical energy and heat in the future. The construction of planar-type SOFC requires bipolar interconnects which separate air and fuel flows and provide both electrical contact and mechanical support for the cells in a stack. The reduction of SOFC operating temperatures to the 923–1073 K range made it possible to employ cost-effective metallic interconnects such as ferritic stainless steel (FSS).

In real SOFC operating conditions, exposure to air (cathode side) and the Ar-H<sub>2</sub>-H<sub>2</sub>O mixture (anode side) occurs at the opposite sides of the interconnect (dual atmospheres). This means that the distribution of the chemical potential of oxygen and hydrogen inside the interconnect is different than in the case of separate oxygen and hydrogen atmospheres (single atmosphere).

In this work, the oxidation behavior of the Crofer 22 APU FSS in a dual atmosphere is investigated. The results obtained for various oxidation times are compared with those obtained under corresponding conditions in single atmospheres. In each case, the oxidation of the examined steel follows the parabolic rate law. The analysis of the morphology, phase, and chemical composition indicates that the presence of gradients of chemical potentials of oxygen and hydrogen to a great extent determines the products of oxidation. The theoretical explanation of oxidation mechanisms is presented.

**Fig. 1.** SEM results obtained after 1000 hrs at 1073K for different areas of the oxidized samples from both air and fuel sides.

Additionally, a non-uniformity of scale thickness is observed on the fuel side. This phenomenon is explained via numerical modeling of gas flow in an experimental setup.

**Fig. 2.** Model of gas flow in an experimental setup. The distribution of static gas pressure on the sample's surface is presented.

# Electrochemical performance of double perovskite $\text{Pr}_2\text{NiMnO}_6$ as cathode for intermediate temperature solid oxide fuel cells

ZHAO Hui, SUN Liping, LI Huan, HUO Lihua

Key Laboratory of Functional Inorganic Material Chemistry, Ministry of Education, School of Chemistry and Materials Science, Heilongjiang University, Harbin 150080 P. R. China Address

e-mail: zhaohui98@yahoo.com

In order to explore the feasibility of non-cobalt cathode materials for IT-SOFCs, we intend to investigate the high-temperature electrochemical properties of B-site ordered double perovskite materials  $\text{A}_2\text{BB}'\text{O}_6$  with Ni and Mn located alternatively in B and B' site. The specific alternating arrangement of B and B' cations in  $\text{A}_2\text{BB}'\text{O}_6$  structure can be of great interest from the catalytic point of view, since the electrocatalytic properties are generally determined by the nature, oxidation states and the relative arrangement of B-site cation. In this sense, double perovskite oxide  $\text{Pr}_2\text{NiMnO}_6$  was studied as the cathode material for IT-SOFCs. The reactivity test indicated that no reaction occurred between  $\text{Pr}_2\text{NiMnO}_6$  and CGO at temperatures up to 1200 °C in air. The thermal expansion coefficient (TEC) of  $\text{Pr}_2\text{NiMnO}_6$  is  $10.6 \times 10^{-6} \text{ K}^{-1}$  in air and  $11.5 \times 10^{-6} \text{ K}^{-1}$  in nitrogen atmosphere within a temperature range of 100-800 °C. The electrochemical properties of  $\text{Pr}_2\text{NiMnO}_6$  cathode was characterized by ac impedance and dc polarization methods, respectively. The lowest area specific resistance (ARS) of  $\text{Pr}_2\text{NiMnO}_6$  cathode is  $0.38 \Omega \text{ cm}^2$  at 700 °C in air. The dependence of ASR with oxygen partial pressure indicates that the charge transfer process is the rate-limiting step for oxygen reduction reaction on  $\text{Pr}_2\text{NiMnO}_6$  cathode.

Fig. 1 The XRD patterns of  $\text{Pr}_2\text{NiMnO}_6$  with YSZ and CGO after calcined at 1200°C for 12h in air

Fig.2 The thermal expansion curves of  $\text{Pr}_2\text{NiMnO}_6$  in (a) air and (b) nitrogen atmosphere

Fig.3 Nyquist plot of  $\text{Pr}_2\text{NiMnO}_6$  cathode under various oxygen partial pressures measured at 700°C. Inset shows the dependence of polarization resistance on oxygen partial pressure at 700°C.

The development of high-temperature polymer electrolyte membrane fuel cell (HT-PEMFCs, working at 150-200 °C) has been done worldwide in order to solve some of the problems of current cells based on Nafion® (CO tolerance, kinetics, water management, etc.). These problems can be overcome by HT-PEMFC, which has been shown to provide several benefits compared to low temperature operation, such as increased kinetics of the oxygen reduction reaction, greater tolerance of the platinum catalyst to CO and better heat management so that the cooling and hydration system can be simplified.

For HT-PEMFCs, the main issue is to develop a proton-exchange membrane with high proton conductivity, high chemical stability, and high mechanical strength at high temperatures and low humidification. Development of thermally stable polymer electrolyte membranes with higher proton conductivity as well as mechanical stability is a key challenge in commercializing PEM fuel cells operating above 100 °C. So far, polybenzimidazole (PBI) membranes have been satisfying good characteristics at temperatures up to 200 °C.

The proton conductivity of phosphoric acid (PA) doped PBI membranes highly depends on the acid doping level (ADL) of the membranes, defined as the mole number of PA per molar repeating unit of the polymer. However, high doping levels often cause excess swelling or even complete loss of the mechanical strength of the membranes due to the strong plasticizing effect of the dopant. The aromatic polyimides (PIs) is another family of engineering plastics well known for their excellent thermal stability, high mechanical strength and modulus, superior electrical properties and good chemical resistance. Polyimide (PI) units are expected to be able to improve the mechanical strength due to their relatively weak interactions with the doped acid molecules in comparison with benzimidazole units.

In this study, the porous polyimide membranes containing benzimidazole were prepared in order to increase the mechanical strength and proton conductivity for HT-PEMFC. The poly(imide benzimidazole)s was synthesized, and the porous membranes was fabricated by porogen. The porous polyimides membranes containing benzimidazole were investigated in terms of ionic conductivity, ADL, FT-IR, mechanical strength, etc.

Electron exchange between conducting surfaces and immobilized redox enzymes can be accomplished either by direct electron transfer (DET), or by a pathway involving redox-active mediating compounds (MET). In our recent papers we reported the liquid-crystalline lipid cubic phase [Fig 1] as a convenient matrix for incorporating enzymes and holding them on the electrode surface in a fully active form. Biofuel cells based on cubic phase do not need additional separating membranes and can be easily miniaturized. The lipidic membrane is biocompatible and stable in the presence of water. <sup>[1, 2]</sup>

We report on the fabrication and characterization of sugar/oxygen based biofuel cells (BFC) operating in neutral sugar containing buffer. Two enzymes have been related as anode and two as cathode materials for the biofuel cell.

*Corynascus thermophilus* CDH (CtCDH)<sup>[3]</sup> and *D-fructose dehydrogenase* (FDH) are catalyzing oxidation of carbohydrates. Their efficiencies were compared to that of Zinc in the hybrid fuel cell. *Myrothecium verrucaria* bilirubin oxidase (MvBOx) and *Cerrena Unicolor* Laccase (Lc) were used as the cathodic bioelements.

[\\*philippe.vernoux@ircelyon.univ-lyon1.fr](mailto:philippe.vernoux@ircelyon.univ-lyon1.fr)

Performances of Solid Oxide Fuel Cells (SOFCs) were investigated in triode operation mode under methane steam reforming in presence of H<sub>2</sub>S. Both the catalytic performances for methane steam reforming and the electrochemical properties of the anode are drastically dropped by the presence of H<sub>2</sub>S impurities introduced through the use of fuels such as natural gas. Indeed, typically 1-30 ppm H<sub>2</sub>S content can be observed in natural gas. Conventional Ni-based cermet anode exhibit strong deactivation when exposed to few ppm H<sub>2</sub>S. This loss is generally attributed to sulfur adsorption on Ni active sites.

Triode operation is a novel approach for enhancing the performances of fuel cells and electrolyzers. This concept is based on the introduction of a third electrode (auxiliary electrode) in addition to the conventional anode and cathode. This auxiliary electrode is located at the cathode side, as shown in the following figure:

Electrodes were deposited by screen printing of commercial powders (Marion Technologies) on YSZ discs (Dynamic Ceramic, 8% mol Y<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub>) with diameter of 20 mm and 1.6 mm thickness. The anode electrode was a Ni/GDC film of 40 μm thickness and a surface area of 1.76 cm<sup>2</sup> and was sintered at 1250°C for 2 hours. The cathode and the auxiliary electrodes were composed of LSM oxides (La<sub>0.65</sub>Sr<sub>0.35</sub>MnO<sub>3</sub> - fuel Cell Materials, LSM35) mixed with YSZ (Tosoh). The cathode was a ring shaped electrode at the periphery of 0.93 cm<sup>2</sup> surface area, and the auxiliary was a circular dot electrode of 0.31 cm<sup>2</sup> surface area at the center of the cathode but separated from the cathode. They were sintered at 1150°C for 2 hours.

To study the performances of the bottom cells, we have used a test rig (ProboStat, NorECs, Netherland). The sealing between the anodic and cathodic compartments was ensured by a gold ring which was annealed at 1040°C for 4 days under air. For current collection, Pt meshes were used for cathode and auxiliary while Ti mesh, catalytically inactive, was used for anode. Prior to the experiments, the catalysts were reduced under pure H<sub>2</sub> at 900°C for 2 hours. The effect of the addition of H<sub>2</sub>S in the reaction mixture has been investigated (1 ppm of H<sub>2</sub>S/He, 2%CH<sub>4</sub>/He – Air Liquide, 5% H<sub>2</sub>O added with a thermostated water saturator regulated at 33 °C) under 200cc/min flow while cathode and auxiliary were exposed under synthetic air (Linde 99,995%). The products of the reaction were analyzed by using a Hiden Analytical HPR20 quadripole mass spectrometer.

H<sub>2</sub>S poisoning was followed in open circuit mode, in fuel cell mode and in triode operation mode at 900°C. Triode operation cannot avoid or limit the catalytic degradation of the SOFC cell exposed to 1 ppm H<sub>2</sub>S but can maintain higher anodic electrochemical performances. This confirms that active sites for catalytic conversion (methane steam reforming) and those for electrochemical oxidation of hydrogen are not the same. The cell performances loss is mainly attributed to the degradation of the catalytic activity, then decreasing the concentration of electroactive species, i.e. hydrogen. Triode operation can slightly compensate the deactivation of the catalytic sites most probably with a local production of H<sub>2</sub>, from H<sub>2</sub>O electrolysis. Some specific triode operations can be found to achieve a thermodynamic efficiency close to the unity to avoid any energy overconsumption.

## 1. INTRODUCTION

Pt is utilized as a catalyst for polymer electrolyte fuel cells (PEFCs). However, because Pt is a novel metal, a method must be devised to reduce its required amount in PEFCs. A widely-studied solution for reducing the amount of Pt is to employ a binary catalyst composed of both Pt and Pd. The addition of Pd is suggested to reduce the amount of required Pt without lowering the activity of the catalyst. This catalyst is generally used in the form of nanoparticles that are dispersed uniformly on a carbon black support in order to increase a surface area of the catalyst. However, the surface area of the dispersed Pt on a carbon black support is smaller due to its tendency to aggregate. We have used Marimo carbon as an alternative for a catalyst support [1]. Marimo carbon is a spherical carbon that is composed of carbon nanofilaments (CNFs). Catalysts can therefore be supported in a highly dispersed form on the CNFs. Consequently, there is an expected increase in the surface area of the Pt, which can also increase its likelihood in contributing positively towards the reaction. In this study, we evaluated the efficacy of a Pt-Pd binary catalyst supported on Marimo carbon.

## 2. EXPERIMENTS

The Marimo carbon was synthesized by thermal chemical vapor deposition (CVD) method. The oxidized diamond supported Ni catalyst were heated at 550 °C for 3 hours in a quartz reactor with methane gas flow. Preparation of the catalyst was accomplished with a modified, nanocolloidal solution method. Marimo carbon was first dispersed in an aqueous solution of sodium hydroxide. After the addition of citric acid to disperse the metal ions and a mixed solution of Pd chloride and chloroplatinic acid were then added. Finally, a solution of sodium borohydride was added to the mixed suspension as a reducing agent, and the Marimo carbon supported Pt-Pd catalyst (Pt-Pd/MC) was obtained[2].

## 3. RESULTS AND DISCUSSION

The scanning electron microscope (SEM) image of the Pt-Pd/MC is shown in Figure 1. The structure of the Marimo carbon was preserved even after the preparation of the catalyst. The binary metal nanoparticles appeared as multiple white spots on the surface of the CNFs. Figure 2 displays the TEM images of the prepared catalyst. The nanoparticles of the catalyst were observed on the CNFs of the Marimo carbon. In particular, nanoparticles ranging from 2~6 nm exhibited a high dispersion on the support. The approximate feed ratio of Pt to Pd was calculated based on spectral peaks obtained from energy dispersive X-ray spectroscopy. On the basis of these results, the utilization of a modified, nanocolloidal solution methodology to form Marimo carbon supported Pt-Pd nanoparticles proved to be a suitable methodology for catalysis.

## 1. INTRODUCTION

Polymer electrolyte fuel cells (PEFCs) can function with a high efficiency for fast start-up time. Platinum nanoparticles supported on the high surface area of nanoporous carbon materials (Pt/CB) are primarily used as a catalyst in PEFCs. However, there are two key technical challenges, (i) the ORR activity needs to be enhanced in order to reduce the overall expense from the high platinum loading amounts, and (ii) the long term durability of the catalysts must be improved in order to extend the operational lifetimes of the catalyst [1]. We have applied Marimo carbon as a catalyst support for the PEFCs. The Marimo carbon is composed of many carbon nanofilaments (CNFs), and the CNFs are interwoven to form a spherical secondary shape. This structure should be favorable toward its utilization in PEFCs. In this study, we prepared MEAs using a Pt catalyst supported on the Marimo carbon (Pt/MC) and/or conventional carbon black (Pt/CB) and investigated the performance of the PEFC.

## 2. EXPERIMENTS

The Pt/MC was prepared by a modified nanocolloidal solution method [2]. MEAs with an active area of 25 cm<sup>2</sup> were prepared using the Pt/MC and/or commercial Pt/CB. Catalyst inks were prepared by mixing a carbon support catalyst with a 5% Nafion solution in deionized water. The weight ratio of carbon to Nafion (I/C) was 0.14 (in the case of Pt/MC) and 0.74 (in the case of Pt/C). These inks were painted with a brush onto the decal surface of the Teflon sheets. Spraying was controlled to result in a catalyst layer with a Pt loading of 0.2 mg<sub>Pt</sub> cm<sup>-2</sup>. Anode and cathode catalyst decals were then hot-pressed onto the opposite sides of a Nafion 212 membrane at 11.5 kN and 428 K for 10 min. The combination of the anode and cathode decals were (A) Pt/CB in anode and Pt/CB in cathode, (B) Pt/CB in anode and Pt/MC in cathode and (C) Pt/MC in anode and Pt/MC in cathode. I-V performance curves of single cell MEAs was carried out at 353 K under a controlled atmosphere. Reactant gas flows were fixed at 200 SCCM for both the H<sub>2</sub> and air.

## 3. RESULTS AND DISCUSSION

Figure 1 shows I-V performance curves for each of the MEAs. The Pt/MC (B and C) gave a higher maximum current density in comparison to the Pt/CB (A). This property can be attributed to the weave structure of the CNFs. If Marimo carbon is used, the reactant gases and the produced water can easily diffuse into the unique structure of the catalyst layer. This characteristic decreases the diffusion polarization, and also increases the maximum current density. The activation polarization (the slope of the lower current density region in the I-V curve) was calculated for each of the anode/cathode combinations, and it was determined that Pt/MC (C) < Pt/CB (A and B). The activation polarization depends on the Pt catalytic activity on the carbon surface. In the case of the carbon black support, some of the Pt catalysts were supported on the surface of the inner pores. The porous structure of carbon black suppressed contact between the Pt catalyst and reactant gases, which thus caused a decrease in the catalytic activity of the Pt particles on the inner pore surface. In the case of Pt/MC, the structure of the Marimo carbon didn't suppress the activity of the Pt particles on the CNF surface. This unique structure of Marimo carbon imparts a superior single cell performance in comparison to carbon black.

# The Effect of Heat-Treatment on the Oxygen Reduction Reaction Activity of Carbon-Supported PtCoAg Electrocatalysts

Zi-Jun Lin, Hong-Shou Chen, Yu-Ting Liang, Kuan-Wen Wang\*

*Institute of Materials Science and Engineering, National Central University, No.300, Zhongda Road, 32001, Taoyuan, Taiwan  
e-mail: kuanwen.wang@gmail.com*

Carbon-supported PtCoAg nanoparticles (NPs) were synthesized and applied as electrocatalysts for oxygen reduction reaction (ORR). In order to improve the activity and stability, the catalysts were heat-treated in  $H_2$  in the temperature range between 420 and 570 K (named as H-420, H-470, H-520 or H-570). The catalysts were characterized by X-ray diffraction (XRD), X-ray absorption spectroscopy (XAS), Transmission Electron Microscopy (TEM) and electrochemical measurements. The numbers of unoccupied d-states ( $h_{Ts}$ ) values of PtCoAg NPs obtained from XAS show that the catalysts with lower  $h_{Ts}$ , have lower unfilled d-states, weaker Pt-O bonds, and less Pt oxide formation, leading to the promotion of ORR kinetics. The optimal heat-treatment temperature was found to be 470 K, where the highest ORR catalytic activity and lowest  $h_{Ts}$  were obtained. H-470 has superior ORR activity to as-prepared and other heat-treated PtCoAg NPs as displayed in Figure 1, and its mass activity (MA) at 0.9 V is 50 times higher than that of as-prepared PtCoAg NPs. After 1000 cycles of accelerated durability test (ADT) under  $O_2$ , the ORR activity of H-470 is higher than that of as-prepared one with a decay of 50.6 vs. 99.9 %. The enhancement of ORR stability may be due to the effect of heat-treatment on the structure and electronic states of Pt for H-470 catalysts.

Figure 1 The linear sweep voltammetry(LSV) results of as-prepared and heat-treated PtCoAg catalysts.

# Mathematical Model of Non-Uniform Cathode Catalyst Layer on the Performance of PEMFC

The distribution of materials property in the catalyst layer is studied. The cathode catalyst layer is divided into three equal spaced layers with uniform property in each layer. The tri-layer is sandwiched between the gas diffusion layer and the membrane for the evaluation of cathode electrode performance at various degrees of humidification (please see the Figure). Each catalyst layer is characterized by the agglomerate size, gas porosity, and void fraction of electrolyte within the agglomerate. The agglomerate is composed of carbon supported platinum (Pt/C) dispersed in the solid electrolyte. In the model, oxygen gas dissolves in the outer liquid film of the agglomerate, diffuses across the film, diffuses into the electrolyte in the void of the agglomerate, and reacts on the surface of Pt/C. For the tri-layer catalyst layer studied, better cell performance is obtained if smaller gas porosity, lower electrolyte fraction within the agglomerate, and larger agglomerate size are concentrated to the face of membrane.

Anion exchange membrane fuel cells (AEMFCs), potentially operated with non-precious metal catalysts, are actively studied. To achieve higher performances of AEMFCs, understanding the ion transport mechanism and the structures of ion conductive paths is important. Current-sensing atomic force microscopy (CS-AFM) has attracted attentions for its capability of observing the surface morphology and ion conductive regions on ion-conductive electrolyte membranes on the nanometer scale. At present, most of these studies have been carried out on proton exchange membranes; few results were reported on AEMs, and the surface anion conductivities are still unclear.<sup>1)</sup> In this study, by using CS-AFM under a temperature/humidity controlled CO<sub>2</sub>-free air, the surface morphology and the current distribution were simultaneously observed on the AEM surfaces.

Two membranes, QPE-bl-3 (IEC=1.80 meq g<sup>-1</sup>) and QPAF-1 (IEC=1.18 meq g<sup>-1</sup>), (Fig. 1) were synthesized in our laboratory, where QPE-bl-3 is a block copolymer whereas QPAF-1 a random copolymer. The membrane was pressed on a gas-diffusion electrode (GDE) with a catalyst layer composed of Pt/C and a commercial binder (AS-4, Tokuyama Corp.). The membrane on the GDE was installed in a homemade environment-control chamber.<sup>2)</sup> CS-AFM measurements were carried out in ultrapure air at temperature of 40 °C and humidities of 50% and 70% RH. Topographies and current images were obtained by using a Pt-coated cantilever at the contact mode with the contact force of 10 nN.

Fig. 2 shows topographies and current images obtained on the two AEMs at 40 °C and 70% RH. The surface of QPE-bl-3 (Fig. 2a) was very flat with the maximum height difference of only 20 nm in the scanned area of 1 μm x 1 μm. The surface of QPAF-1 (Fig. 2b) was also flat, but small, nanometer corrugations were observed over the surface. Fig. 2c shows the current image on QPE-bl-3. Large anion conductive regions and non-conductive regions of tens of nanometers were separately observed. In the current image on QPAF-1 (Fig. 2d), highly-dispersed small anion conductive spots were observed. Profiles of the membranes, such as the ratio of anion conductive areas, the pseudo average current densities, and the cross sectional current distributions, were systematically and statistically studied on the two membranes. The difference in the performances of the power generation using the two AEMs was correlated with the difference in those surface properties of the membranes.

[1515701@ed.tus.ac.jp](mailto:1515701@ed.tus.ac.jp)

Acceptor-doped perovskite-type oxide  $\text{Y}^{3+}$ -doped  $\text{BaCeO}_3$  (BCY) bulk crystal exhibits high proton conduction at intermediate temperature (IMT) region under water vapor atmosphere. This proton conduction is expected for electrochemical application of electrolyte of solid oxide fuel cell (SOFC). Furthermore, Matsumoto and co-workers have reported that Ru-doped BCY (BCRY) ceramics exhibit the electron-proton mixed conduction in IMT region [1]. Although the mixed conducting of BCRY can be used as an electrode material of SOFC, the structural and electrical properties of BCRY electrode film have not been clarified thus far. In this study, we have prepared the BCRY thin films with various film thickness on  $\text{Al}_2\text{O}_3$  substrates by RF magnetron sputtering and characterized their structural and electrical properties.

The BCRY thin films were deposited on  $\text{Al}_2\text{O}_3$  substrates by RF magnetron sputtering using ceramics target. The chemical composition of BCRY was  $\text{BaCe}_{0.85}\text{Ru}_{0.05}\text{Y}_{0.10}\text{O}_{3-\delta}$ . The RF power, deposition pressure and substrate temperature were fixed at 80 W,  $4.0 \times 10^{-3}$  Torr, and 600 °C, respectively. The Ar gas flow rate was 20 sccm. The thickness was changed from 20 nm to 300 nm. The structural properties were characterized using X-ray diffraction (XRD). The electronic structures were characterized using photoemission spectroscopy (PES). The electrical conductivity of in-plane direction was measured using AC or DC impedance spectroscopy through the Pt interdigital electrode.

Fig.1 exhibits the XRD patterns of BCRY thin films with various film thickness. These films crystallized without post annealing. The thicker films above ~100 nm exhibit (002) peak of Orthorhombic (*Incn*) structure of  $\text{BaCeO}_3$ . The thinner films below ~50 nm exhibit (002) peak of Orthorhombic (*Pmcn*) structure of  $\text{BaCeO}_3$ .  $\text{BaCeO}_3$  was reported to exhibit structural phase transition from *Pmcn* to *Incn* structures at 563 K [2]. The thin films in this study have *Incn* and *Pmcn* structure by changing film thickness. This indicates that the lattice constant of *c*-axis changes largely by film thickness due to the lattice mismatch between BCRY film and  $\text{Al}_2\text{O}_3$  substrate. Therefore, the proton and electron conductivities of BCRY thin films are indicated to be effected by the film thickness.

In this presentation, the author will show details of electrical conductivity, electronic structure of BCRY thin films and discuss about the electron-proton conduction of BCRY thin films.

# Pt/C Trapped in Activated Graphitic Carbon Layers as a Highly Durable Electrocatalyst for Oxygen Reduction Reaction

Yao Nie, Siguo Chen, Wei Ding, Xiaohong Xie, Yun Zhang, Zidong Wei\*

Chongqing Key Laboratory of Chemical Process for Clean Energy and Resource Utilization, School of Chemistry and Chemical Engineering, Chongqing University, Chongqing, 400044; China  
zdwei@cqu.edu.cn

Proton exchange membrane fuel cells (PEMFCs) have drawn significant attention as a novel alternative to traditional power sources due to their high energy conversion efficiency and low environmental impact<sup>[1]</sup>. At present, the most commonly used cathode catalysts are highly dispersed 2-5 nm Pt nanoparticles (NPs) supported on carbon. However, the insufficient electrocatalytic activity and durability of Pt cathode catalysts still remains a major obstacle for PEMFCs applications<sup>[2]</sup>. Seldom reports have focused on enhancing the structural integrity and the corrosion resistance of Pt-based catalysts by covering Pt nanoparticles surface with an active sites-containing layer to realize both superior durability and high activity. In this work, we designed a novel strategy to address both durability and activity issues via coating a nitrogen-containing graphitic carbon (NGC) layer onto the surface of Pt/C catalyst (Pt/C@NGC). The NGC, which is usually employed as an ameliorative carbon support or a promising Pt-free ORR catalyst<sup>[3,4]</sup>, is elaborately introduced to the Pt/C surface to not only inhibit migration and dissolution of Pt nanoparticles, but also act as the secondary active site supplier that imparting activity to the integral catalyst without blocking the inner Pt catalytic active sites. Corrosion of carbon support also can be alleviated due to the protection of the outer graphitic cover. Moreover, the NGC precursor, polyaniline, was ingeniously used to inhibit Pt NPs from serious sintering, thus guaranteeing the feasibility of the design concept of the Pt/C@NGC. This new nanoarchitecture, incorporating simultaneously above desirable design rationales, exhibits much improved durability and activity over commercial Pt/C for ORR.

# Shape Fixing via Salt Recrystallization: A Morphology-Controlled Approach to Convert Nanostructured Polymer to Carbon Nanomaterial as a High Active Catalyst for Oxygen Reduction Reaction

Wei Ding,\* Wei Li, Guangping Wu, Li Li, Siguo Chen, Xueqiang Qi, Zidong Wei\*

School of Chemistry and Chemical Engineering, Chongqing University, Shazhengjie 174, Chongqing, 400044, China

zdw@cqu.edu.cn; dingwei128@cqu.edu.cn

The ability to control mesoscale architectures of carbon materials is essential to possess unique functionality that yields faster, cheaper, higher performing, and longer lasting carbon materials for energy conversion and storage, as well as for the development of catalytic materials for the oxygen reduction reaction (ORR). In the past decade, numbers of methods had been developed to control compose, morphology, porosity of macromolecular compounds which can be used as precursor of carbon materials. We aim to build a connection that could accurately transfer macromolecular compounds to carbon materials by simply pyrolysis without destroying the original architectures. This will provide a powerful and facile method to control mesoscale architectures of carbon materials, and will derive many interesting carbon materials. We report a “shape fixing via salt recrystallization” method to accurately transfer self-assembled polyaniline to the final N-doped carbon materials by fixed and fully sealed inside NaCl crystal via recrystallization of NaCl solution. We demonstrated that the N-doped carbon materials with 3D network, nanotube, and nanoshell morphology are realized by the invented method. The NaCl crystal provides a fully closed nanoreactor, which changes the behavior of transition from precursor to carbon materials, and facilitates N incorporation and graphitization during pyrolysis. Use of the invented N-doped carbon material as cathode catalyst in a proton exchange membrane fuel cell produces a peak power of  $600 \text{ mWcm}^{-2}$ , making this among the best non-precious metal catalysts for the oxygen reduction reaction reported so far. This greatly improved performance can be attributed to the unique advantages of this method, which achieves a high microporosity, with a high density of ORR active-sites located along the efficient mass transport pathway (composed of meso- and macropores), resulting in a high utilization of active-sites. This developed method provides a simple but efficient and versatile approach to the construction of carbon nanomaterials with controlled porous structures and morphologies, for industrial purposes ranging from catalysis and sensors to supercapacitors and lithium-ion batteries.

<sup>2</sup>*Department of Chemistry, University of Warsaw, Pasteura 1, 02-093 Warsaw, Poland*

Nowadays a variety of aspects concerning the polymer electrolyte membrane fuel cells is extensively studied. The structure of electrocatalyst layer (architecture) is crucial as it determines the mass-transport processes encountered during the electrochemical processes [1]. In the preparation of the catalysts tested in oxygen reduction reaction (ORR) a commonly used method is based on the preparation of an ink composed of the catalyst powder and Nafion ionomer (perfluorosulfonic acid). The role of acid/alkaline functionalities of supports in modification of noble metal particles reactivity has been well documented in various types of reactions carried out on heterogeneous catalysts [2]. Thus, it may be expected that the presence of the Nafion acid functionalities in a close proximity to the Pt, Pd-nanoparticles, as in the ink, would affect their chemisorption properties via electron modification. However, to the best of our knowledge the Nafion – Pt, Pd interaction effect has not been taken yet into consideration in discussing the results of ORR on Pt, Pd-electrocatalysts.

Present studies concentrated on the preparation, characterization and electroactivity of palladium – polypyrrole (Pd/PPY) catalysts for ORR. In particular, the effect of Nafion ionomer on their electroactivity was evaluated. The results were reported in our work [3, 4]. In all catalysts prepared by the “water-in-oil” microemulsion method, the Pd nanoparticles of ca. 7 nm in size appeared regardless of the Pd content (ranging from 2 to 20 wt.%). For comparison, carbon black (Vulcan XC-72) supported catalyst (20 wt.% Pd) was also synthesized. Mixing of the Pd/PPY samples with Nafion ionomer reduced their surface area and porosity. The microporous structure was preferentially blocked whereas some changes in the mesoporous structure resulted in decreased average pore diameter. Chemical interaction due to Nafion acid functionalities affected the N-state of pyrrole as well as electron state of Pd in the Pd/PPY catalysts. These interactions played an essential role in the electroactivity of Pd/PPY catalyst for ORR. The increased amount of Nafion relative to that of PPY reduced limiting current density whereas the half-wave potential shifted to more positive value (Fig. 1) and the fraction of hydrogen peroxide remarkably decreased. The observed enhanced ability of the Pd/PPY catalyst towards oxygen reduction via 4-electron pathway might arise from modification of Pd-sites reactivity induced by the presence of Nafion.

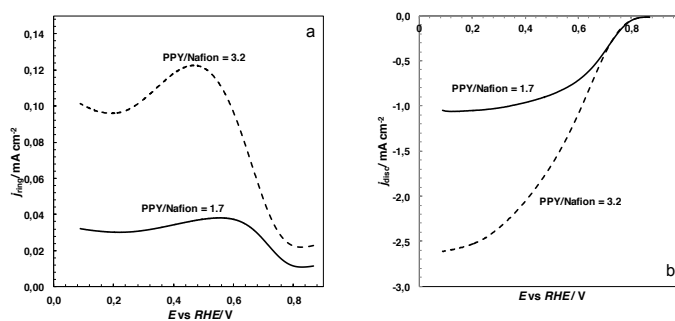

Fig. 1. Normalized (background subtracted) rotating **a** ring and **b** disc voltammograms for ORR on 20 % Pd/PPY catalyst mixed with Nafion, with PPY/Nafion weight ratio of 3.2 (dashed lines) and 1.7 (solid lines). Electrolyte: 0.5 M H<sub>2</sub>SO<sub>4</sub>. Rotation rate: 1,600 rpm. Scan rate: 5 mV s<sup>-1</sup>

# Graphene-Carbon Nanofibers Composite Film As a Highly Active Catalyst Support for Formic Acid Electrooxidation

Xuan Jian, Xian Liu, Yang huimin, Zhenhai Liang\*

College of Chemistry and Chemical Engineering, Taiyuan University of Technology

No.79 west Yingze street, Taiyuan, Shanxi, China, 030024

e-mail: [liangzhenh@sina.com](mailto:liangzhenh@sina.com); [liangzhenhai@tyut.edu.cn](mailto:liangzhenhai@tyut.edu.cn)

**Abstract:** Direct formic acid fuel cells (DFAFCs) was superior in fuel cells and had aroused more concerns<sup>[1-2]</sup>. It was generally known that the performance of a catalyst layer in a fuel cell was influenced by dispersivity and stability of nanoparticles on the surface of support materials. So, seeking novel catalyst support materials for DFAFCs had became one of the research hot topics in DFAFCs fields<sup>[3]</sup>.

In this study we had demonstrated the preparation of a novel composite film using the excellent electric properties of graphene (GR) and the unique advantages of carbon nanofibers (CNFs). The CNFs was fabricated through the template-directed by using ultrathin Te nanowires as templates and glucose as carbon source<sup>[4]</sup>. Graphene oxide was dropped on the glass carbon electrode (GCE) and reduced by direct electrochemistry in N<sub>2</sub>-saturation 0.1 M KCl solution. Pt-Pd bimetallic catalysts had been deposited on the graphene-CNFs composite film modified GCE by cyclic voltammetry (CVs).

The electrocatalytic properties of different modified electrodes were measured shown in Figure 1. Both the hydrogen adsorption/desorption region and PtPd bimetallic catalysts oxide reduction region can be observed in the Figure 1A. The peak current in the Figure 1B for the PtPd/GR/CNFs was 3.38 mA, which was approximately twice of the PtPd bimetallic catalysts directly deposited on the naked GCE (1.64 mA). The results indicated that the addition of GR/CNFs composite film as catalyst support greatly improved not only Pt-Pd nanoparticles deposition (Figure 1A), but also the catalytic activity for formic acid electrooxidation (Figure 1B).

**Figure 1: A.** CVs of Pt-Pd bimetallic catalysts modified different substrate electrodes in 0.5 M H<sub>2</sub>SO<sub>4</sub> solution at 50mV·s<sup>-1</sup>.

**B.** CVs of Pt-Pd bimetallic catalysts modified different substrate electrodes in 0.5 M H<sub>2</sub>SO<sub>4</sub> and 0.5 M HCOOH solution at 50mV·s<sup>-1</sup>.

*(E-mail: leems@kolon.com)*

Stability of polymer electrolyte membrane stands out always important issue as well as proton conductivity. The reinforced membrane can be a good solution to enhance the mechanical and dimensional stability for not only perfluorosulfonic acid polymer but also hydrocarbon based polymer. In this study, we have prepared nanofiber reinforced polymer electrolyte membranes for proton exchange membrane fuel cells. The nanofiber reinforced PEMs was impregnated by introducing hydrocarbon polymer electrolytes into nanoweb substrate. Due to high porosity and the intrinsic structure of reinforced PEMs, mechanical and dimensional stability are improved without sacrificing membrane performance. Consequently, reinforced PEMs exhibited higher physical properties than neat PEMs. The results suggested that the nanofiber reinforced PEMs could be utilized as an alternative proton exchange membrane for fuel cell applications.

In a polymer electrolyte membrane fuel cell, the membrane is subjected to a chemically oxidizing environment at the cathode and a chemically reducing environment at the anode. Formation of hydrogen peroxide and gas crossover reactions can lead to radical formation in the fuel cell. The formation of H•, HO• and HOO• radicals has been proven by ESR. Detection of these radicals, together with the carbon center radical, showed the possibility of radical attack as the source for the chemical degradation of the polymer. A variety of in-situ and ex-situ analyses were used for studying the chemical degradation of the membrane. Ex-situ Fenton's reagent tests provide a mixture of oxidative radicals, HO• and HOO•, while in-situ fuel cell operation yields both oxidative radicals, HO• and HOO•, and the reductive H• radical.

In this work,<sup>1</sup> electron beam (e-beam) irradiation is used to selectively generate H• and HO• radicals. ESR analyses of irradiated solutions containing spin traps confirm the selective formation of individual radicals. Nafion® membrane, exposed to each radical separately, was characterized by solid state <sup>19</sup>F NMR. Changes in molecular structure were detected for different portions of the polymer chain. The changes in ion exchange capacity and proton conductivity were monitored before and after irradiation. It was shown that the chemical structure of the polymer is sensitive to both oxidative and reductive radicals. The position of attack for the oxidative HO• radical is the C-O bond closer to the end of the side chain. The position of attack for the reductive H• radical is the tertiary carbon in the main chain and the side chain. While the possibility for the formation of oxidative radicals in the fuel cell is higher, the H• radical appears to cause more damage.

The anion exchange membrane fuel cells (AEMFCs) provide the possibility to use non precious metals as the electrode catalysts in the cells. Due to this main advantage, AEMFCs and correlative materials have attracted extensive attentions<sup>[1-2]</sup>. The anion exchange membrane (AEM) is one of the most key components, whose properties determine the performance of the AEMFCs. AEMs which possess more quaternary ammonium groups could exhibit high conductivity. However, significant swellings and decreased mechanical strength may also connect with the high content of the quaternary ammonium and thus deteriorate the durability of the membranes<sup>[3,4]</sup>.

Fig. 1 Chemical structure of di-imidazolium cation crosslinked poly(2,6-dimethyl-1,4-phenylene oxide)

In the present work, novel AEMs based on cross-linked poly(2,6-dimethyl-1,4-phenylene oxide) (PPO) were fabricated and investigated. Bromomethylated PPO (BPPO) polymers with a bromination degree of 71% were first synthesized by bromination of the alkyl side chains. The crosslinked membranes were then prepared from BPPO, methylimidazole and 1,4-bis(imidazolyl)butane. The membranes with various degree of cross-linking could be obtained by adjusting the molar ratio of methylimidazole and 1,4-bis(imidazolyl)butane. FTIR and TGA measurements confirmed the occurrence of the crosslinking reaction. The experimental results indicated that the conductivity, water uptake and swellings of the membranes increased as the increased content of methylimidazole in the membranes. The high hydrophilicity of the PPO with a methylimidazolium grafting degree of 100% resulted in high solubility of the membrane in water, especially at elevated temperatures. However, crosslinked membranes with crosslinking degrees from 10% to 100% were rather stable and could be used as AEMs. The membrane with a crosslinking degree of 10% exhibited the highest conductivity of 39 to 55 mS cm<sup>-1</sup> in water over a temperature range 60 - 80 °C. The results indicated that the bi-imidazolium cation crosslinked membranes have the potential to be used as membrane electrolytes for AEMFCs.

## ABSTRACT

Fuel cells, power generation devices, have been recognized as one essential solution to diminishing supplies of fossil fuel, environmental pollution, and global warming. Fuel cell technology has enjoyed great advancement in the last few years being in our days a reality for automation application.

In this work, particular attention is paid to the local analysis of performance and degradation of cells operated under a synthetic cycle for bus application. This cycle it seems to be very aggressive with fast and high changes in current load between 0.2A/cm<sup>2</sup> and 1.4 A/cm<sup>2</sup> the cell was run approximately for 300h under. In order to study locally the degradation influence of inlet gas humidification on cell performance all the experiments were performed with the DLR- PCB segmented cell current density measurements, other global effect were studied using in-situ diagnostic tools, such as cyclic voltammetry. The changes observed locally in the current densities distributions were investigated locally by post-mortem ex-situ investigations by XPS to determine changes in the chemical composition of the different layers during the experiment

Figure 1 Comparison of the voltage responses and current density distributions at the beginning and after 300h of the bus application cycle.

# Characterization of ultra-low loading MEAs fabricated by electrospray deposition

## ABSTRACT

Ultralow Pt-loading electrodes can be manufactured by electro-hydrodynamic atomization of a catalytic ink[1]. MEAs of 25 cm<sup>2</sup> with different catalytic loadings were produced using this technique. Electrodes with 0.02 mgPt cm<sup>-2</sup>, 0.04 mgPt cm<sup>-2</sup> and different Nafion® concentrations were tested in a fuel cell test station fed with hydrogen & air. The best mass-related performance was obtained for an asymmetric MEA with a global load of 0.06 mgPt cm<sup>-2</sup> with a platinum utilization of 3.8 kW grPt<sup>-1</sup> at 0.6 V, 70 °C and 1.5 bar. Analysis under different pressures, relative humidity and gas flow rates were performed using a segmented cell to measure local current distribution and electrochemical impedance spectroscopy (EIS). In addition, long-term operation for 100 hours were also carried out to test the electrode durability. The potential of these MEAs for reduction of noble metal loading is discussed.

Comparison between the MEA2 (blue triangles) and MEA3 (green circles) polarizations curves at Tc: 70°C, Pressure:1.5 bar, Stoichiometry: H2:1.5 Air:2 and RH:100%. Current distributions and EIS plots correspond to a constant current density of 360 mA cm<sup>-2</sup>

The alkaline fuel cells based on the anion exchange membranes (AEMs) have recently attracted much attention mainly due to the possibility for using non-noble metals as the electrode catalyst. As the core component of the fuel cell, the AEMs should satisfy the requirements of high ionic conductivity, sufficient mechanical strength, and superior stability and durability towards strong bases. The most commonly used AEMs are quaternary-ammonium-based polymer membranes<sup>[1,2]</sup>. The AEMs containing quaternary phosphonium<sup>[3]</sup>, imidazolium<sup>[4]</sup> and guanidinium<sup>[5]</sup> groups are also reported. However, There are some challenges to AEMs such as the degradation of the polymer in alkaline medium and slow mobility of the hydroxide ions than that of protons. Therefore development of the AEMs with superior properties is needed.

We synthesized the imidazolium-functionalized cross-linked poly(aryl ether ketone)s (CL-ImPAEKs) to prepare the AEMs. The homemade PAEK polymer was first brominated with a bromination of about 50% (containing four methyl bromides per repeat unit of the PAEK). The brominated-PAEKs were secondly quaternized by conversion of all the methyl bromides into methyl imidazoles. Two imidazoles, i.e., 1-methylimidazole and 2-undecylimidazole with a mole ratio of 4:1 were used to perform the conversion. The employed C2-substituted imidazoles are expected to bring about the AEMs high tolerance towards strong bases. Crosslinking of the polymer via -N= sites of the imidazole rings with different structure of the crosslinkers were performed to obtain the CL-ImPAEKs. The hydroxide form CL-ImPAEK membranes showed conductivities of 0.01 to 0.05 S cm<sup>-1</sup> in water at a temperature range of 25 to 80 °C. The conductivity of the obtained CL-ImPAEK membranes could maintain at least 120 h at 60 °C. The results indicated that the CL-ImPAEK-based membranes have the potential to be used as membrane electrolyte for anion exchange membrane fuel cells.

Long-term reversible charge-transfer for MnO<sub>2</sub>-based pseudocapacitor electrode has up to now been limited to one-electron transfer between Mn(IV) and Mn(III) ion over an operating potential (OPW) not greater than 1 V. A novel material design strategy is demonstrated to substantially widen (up to 2 V) the OPW of MnO<sub>2</sub>-based aqueous pseudocapacitive electrode and to enable two-electron transfer between Mn(IV) and Mn(II) ions sustainable over thousands of cycles. The material design involves, via a facile solution chemistry method, forming spatially confined MnO<sub>2</sub> nanodomains (approximately 4 nm in size) of which the surfaces are surrounded by electrochemically inactive SiO<sub>2</sub> with extensive interfacial Mn • O • Si bonding. The MnO<sub>2</sub> • SiO<sub>2</sub> (MSO) composite electrode exhibits mixed pseudocapacitor • battery behavior with two-electron transfer in an aqueous Li<sub>2</sub>SO<sub>4</sub> electrolyte between • 1 V and 1 V versus Ag/AgCl/saturated KCl and no Mn ion dissolution or phase transformation into more compact lattice structure, which otherwise occur in the conventional bulk MnO<sub>2</sub> electrode and lead to fast charge-storage capacity deterioration, during long-term cycling. In operando synchrotron X-ray absorption analyses reveal a two-step charge-transfer process, consisting of a solid-solution mechanism between Mn(IV) and Mn(III) and a two-phase reaction mechanism between Mn(III) and Mn(II). The presented MSO nanostructure holds great promise for high-capacity, high-energy supercapacitor applications.

Electrochemical capacitors (ECs), also called super-capacitors or ultra-capacitors, are charge storage device with capacities intermediate between those of electrolytic capacitors and rechargeable batteries. ECs store charge at the electrode/electrolyte interface either through conventional non-Faradic means, by forming an electric double layer or by a limited Faradic reaction. The development of high performance capacitors requires improvements in all components such as activate material, electrolyte, binder and cell configuration. Recently, researchers have begun to explore the combination of both Faradic and non-Faradic processes in the same hybrid device to overcome the limits of conventional EDLCs [1-3].

Activated carbons as spheres having high specific surface areas have been used in many applications such as adsorbents and electrode materials of ECs. Activated carbon spheres were prepared by three-step process. First, glucose was carbonized by hydrothermal method using autoclave. Next, obtained carbon spheres were activated with potassium carbonate by chemical activation. Finally, through the heating treatment, activated carbon spheres were obtained. When the heating treatment increases, the capacities increase until 80Fg<sup>-1</sup>. Also, we prepared Li<sub>4</sub>Ti<sub>5</sub>O<sub>12</sub>-CNT composite materials synthesized to enhance of power density of Li<sub>4</sub>Ti<sub>5</sub>O<sub>12</sub>, which is used as a negative active material that has a zero-strain behavior and high charge-discharge performance [4]. The spherical Li<sub>4</sub>Ti<sub>5</sub>O<sub>12</sub> and Li<sub>4</sub>Ti<sub>5</sub>O<sub>12</sub> carbon nanotube (CNT) composites were synthesized using a colloid system. The electrochemical properties of the composites were thoroughly examined to determine their applicability as hybrid capacitor anodes. The spherical Li<sub>4</sub>Ti<sub>5</sub>O<sub>12</sub>-CNT composite electrical conductivity was improved over that of the spherical Li<sub>4</sub>Ti<sub>5</sub>O<sub>12</sub> composite. The synthesized composites were utilized as the anode of a hybrid capacitor, which was assembled with an activated carbon (AC) positive electrode. The CNTs attached on spherical Li<sub>4</sub>Ti<sub>5</sub>O<sub>12</sub> contributed to a 51% reduction of the equivalent series resistance of the Li<sub>4</sub>Ti<sub>5</sub>O<sub>12</sub>-CNTs/AC hybrid capacitor compared to the Li<sub>4</sub>Ti<sub>5</sub>O<sub>12</sub>/AC hybrid capacitor. When applied in a hybrid capacitor, we confirmed the decreasing ESR of the hybrid capacitor. Thus, the LTO-CNT 1wt.% and LTO-CNT 2 wt.% hybrid capacitors had capacities that were 31.6% and 62.7% larger than that of the LTO-AC hybrid capacitor, respectively, in a current density of 10 mA cm<sup>-2</sup> at cycles. The addition of CNTs improved the hybrid capacitor because of the electron path formation in LTO materials. The synthesized composite electrode shows a promising candidate for electrode materials used in high power hybrid capacitors.

Electric double layer capacitors (EDLCs) have attracted great attention as an electric power source because they have a high power density and long cycle life when compared to other power devices, e.g., lithium-ion batteries. We have to, however, improve their performances more for various advanced applications such as a hybrid electric vehicle (HEV) and electric vehicle (EV). We reported that specific power density of EDLC can be improved by applying various natural polymers, e.g., alginate acid (Alg) and chitosan, as a matrix of gel electrolytes [1]. This effect is ascribed to decreased resistances at an interface between an electrode and electrolyte, which is originated from high affinity between the natural polymer materials and carbon materials such as activated carbon.

To enhance and utilize this characteristics we attempted to apply various natural polymers to EDLC as a binder for activated carbon electrodes, and improved their performances [2]. The cell with Alg binder shows high discharge capacitance and excellent rate capability when compared to the other cells with CMC and PVdF binders. This result suggests that the electrode with Alg has a lower internal resistance due to higher affinity between activated carbon and the natural polymer, which reduces a reaction resistance at the electrode/electrolyte interface. This property is consistent well with our previous affinity test [1]. The present merit of Alg binder is also confirmed from the results of AC impedance measurements as follows. Regarding Nyquist plots of each test cell with Alg, CMC, and PVdF binder, in a middle frequency range related to ionic diffusion inside an activated carbon electrode, the cell with Alg binder exhibits desirable characteristics, which should contribute to lower internal resistance. Thus the present natural polymer material is an attractive component in EDLC application to improve its power density, keeping its desirable specific energy.

Recently, we also applied gelatin material to binder in EDLCs. Our gelatin derivatives can keep electrode materials such as activated carbon and conductive materials steady as a important function of electrode binder. Resulting electrode films with gelatin are very strong enough to protect themselves against a manual scratching. An internal electric resistance in the gelatin-applied electrode sheets is somewhat higher than that in CMC-SBR-based electrode sheets. However, not only their mechanical strength but also their resistivity against oxidation, which we found in cell-cycling and cell-floating tests, are quite attractive. The applied electrode can be prepared in aqueous media including gelatin, conductive auxiliaries, and activated carbons. Thus the gelatin-based preparing process can provide us with environmentally friendly, safe and low-cost production for EDLC electrode sheets.

# Pseudocapacitance of ruthenium oxide in buffered solutions

Wataru Sugimoto, Sho Makino

Shinshu University, Center for Energy and Environmental Science  
3-15-1 Tokida Ueda, Nagano, 386-85657 Japan  
wsugi@shinshu-u.ac.jp

Various metal oxides have been proposed as promising electrode materials for aqueous pseudocapacitors. Electrolytes near neutral pH are often used owing to its environmental friendliness and its low corrosiveness. We have recently started to explore buffered solutions as electrolytes for pseudocapacitors. Despite  $\text{RuO}_2$  being the model pseudocapacitive material, the electrochemical capacitor properties of  $\text{RuO}_2$  in neutral electrolytes are less known compared to the behavior in acidic or basic electrolytes. Here we explore the pseudocapacitive behavior of ruthenium oxide nanoparticles and nanosheets in buffered solutions as an environmentally benign electrolyte.

The pseudocapacitive charge storage in poorly-crystalline hydrous  $\text{RuO}_2$  nanoparticles and highly-crystalline  $\text{RuO}_2$  nanosheets derived from layered  $\text{Na}_{0.2}\text{RuO}_{2.1}$  were investigated. Capacitance comparable to or higher than  $\text{H}_2\text{SO}_4$  were obtained in acetic acid-lithium acetate ( $\text{AcOH-AcOLi}$ ) buffered solutions, depending on the ionic strength and pH. At constant pH,  $\text{AcOH-AcOLi}$  with higher ionic strength (molarity) lead to higher capacitance, owing to the presence of higher concentration of the adsorbent in the electrolyte. Figure 1 shows voltammograms of  $\text{RuO}_2 \cdot n\text{H}_2\text{O}$  in various  $\text{AcOH-AcOLi}$  solutions. The cyclic voltammograms for 2.0 M  $\text{AcOH-AcOLi}$  (pH = 5.36) completely overlaps with that in  $\text{H}_2\text{SO}_4$ , implying an analogous charge storage mechanism. On the other hand, the electrochemical behavior in 2.0 M  $\text{AcOH-AcOLi}$  with pH = 4.44 and 3.42 are quite different. For pH = 3.42, the electrical double layer capacitance is completely lost. This peculiarity is attributed to adsorption of molecular  $\text{AcOH}$  (not  $\text{AcO}^-$ ) on the surface of  $\text{RuO}_2$ , blocking the electrical double layer formation.

$\text{RuO}_2$  nanosheets afforded 20 to 50% higher capacitance than  $\text{RuO}_2 \cdot n\text{H}_2\text{O}$ . The highest capacitance is obtained with 5 M  $\text{AcOH-AcOLi}$  (pH=5.4)  $1,038 \text{ F g}^{-1}$  at  $2 \text{ mV s}^{-1}$ , which is almost 1.5 times higher than the benchmark  $\text{RuO}_2 \cdot n\text{H}_2\text{O}$  in  $\text{H}_2\text{SO}_4$  electrolyte ( $720 \text{ F g}^{-1}$ ).  $\text{RuO}_2$  nanosheet electrodes also perform well in bio-electrolytes such as phosphate buffered saline ( $837 \text{ F g}^{-1}$ ) and fetal bovine serum ( $772 \text{ F g}^{-1}$ ).

Figure 1. Cyclic voltammograms of  $\text{RuO}_2 \cdot n\text{H}_2\text{O}$  at 2, 5, 20, 50, 200,  $500 \text{ mV s}^{-1}$  in 2.0 M  $\text{AcOH-AcOLi}$  at pH of a) 3.42, b) 4.44, and c) 5.36. d) Cyclic voltammograms of  $\text{RuO}_2 \cdot n\text{H}_2\text{O}$  at  $2 \text{ mV s}^{-1}$  in 2.0 M  $\text{AcOH-AcOLi}$  with various pH and 0.5 M  $\text{H}_2\text{SO}_4$ .

# Facile Simulation of Electric Double-Layer Capacitance Based on Helmholtz Models

Hsisheng Teng, Wei Hsieh, Hsin-Chieh Huang,

*Department of Chemical Engineering and Research Center for Energy Technology and Strategy, National Cheng Kung University, Tainan 70101, Taiwan*  
*hteng@mail.ncku.edu.tw*

Promoting the charge storage performance of electric double-layer capacitors requires a simulation model for the double-layer formation mechanism as well as the characterization of the electrode-electrolyte interface. Unfortunately, previous models are applicable only to electrodes with a specific pore size. We propose a universal model, based on the Helmholtz theory, to outline the double-layer formation mechanism in carbons with a wide pore size distribution.

In this study, we determine that surface-based capacitance ( $C/S$ ) value of cylinder-like mesopores decreases with a decrease in pore size due to an increase in the influence of wall curvature on ion layering while slit-shaped micropores exhibit constant  $C/S$  values irrespective of pore size. The pore structures and pore size distribution of the carbon are analyzed using a method based on non-local density functional theory (NLDFT). The simulated capacitance values of three distinct forms of carbons present excellent agreement with the experiment data, thereby verifying the reliability and feasibility of the proposed model.

We also present a strategy for the determination of constant  $C/S$  values in micropores. Our findings demonstrate that the number of solvent molecules in such confined spaces decreases with a decrease in slit width, which weakens polarizability at the interface. This model reveals the molecule-sieving effect of micropores, which is critical to the precision of capacitance prediction.

# Oxygen Functional Groups of Incompletely Reduced Graphene Oxides for a Thin-film Electrode of Supercapacitor

Jong-Huy Kim\*, Young-Joon Oh, Jung-Joon Yoo, Yong-Il Kim, and Jae-Kook Yoon  
Korea Institute of Energy Research  
#152 Gajeong-ro, Yuseong-gu, Daejeon, 305-343, KOREA(South)  
kjhy@kier.re.kr

For incompletely reduced graphene oxides (RGOs), an effect of oxygen functional groups such as carboxyl, phenol, carbonyl, and quinone on electrochemical capacitive behavior was studied. To prepare RGO thin-film electrodes, a simple fabrication process by (i) dropping and evaporating the graphene oxide (GO) solution, (ii) irradiating pulsed light, and (iii) heat-treating at 200–360 °C was applied. It was notable that the pulsed light irradiation was effective to prevent the disfiguring of deposited GO thin-film during the thermal reduction.

As increasing the thermal reduction temperature from 200 to 360 °C, interlayer distances of the RGOs obtained from XRD analyses were gradually decreased from 0.379 to 0.354 nm. XPS O 1s spectra analyses showed that the atomic percentages of carboxyl and phenol of the RGOs were sustained as  $5.40 \pm 0.36$  and  $4.77 \pm 0.41$  at% respectively. Meanwhile, those of carbonyl and quinone of the RGOs were gradually declined from 3.10 to 1.81 and from 1.32 to 0.65 at% respectively.

For all RGO thin-film electrodes with different thermal reduction temperature, the specific capacitances at the scan of  $5 \text{ mV s}^{-1}$  were sustained as ca.  $220 \text{ F g}^{-1}$  in 6 M KOH and  $93 \text{ F g}^{-1}$  in 0.5 M  $\text{Na}_2\text{SO}_4$ . However, in 1 M  $\text{H}_2\text{SO}_4$ , the specific capacitance was gradually decreased from 171 to  $136 \text{ F g}^{-1}$  as increasing the reduction temperature. After 100,000 cycles under the scan rate of  $500 \text{ mV s}^{-1}$  but in different electrolytes of 6 M KOH, 1 M  $\text{H}_2\text{SO}_4$ , and 0.5 M  $\text{Na}_2\text{SO}_4$ , the RGO thin-film electrodes reduced at 200 °C exhibited ca. 92, 54, and 104 % of the initial capacitances respectively. The atomic percentages of the oxygen functional groups involved in the pseudocapacitive Faradaic reaction were decreased after the cycle test. Especially in 1 M  $\text{H}_2\text{SO}_4$ , quinone group was decreased to ca. 48 % of initial atomic percentage, which seems to be a main reason for the drastic reduction of capacitance.

At the scan of  $5 \text{ mV s}^{-1}$  the specific pseudocapacitance per unit atomic percentage for either carboxyl or phenol group in 6 M KOH was obtained as  $12.59 \text{ F g}^{-1} \text{ at}\%^{-1}$ . For carbonyl group in 1 M  $\text{H}_2\text{SO}_4$ , it was a slightly deviated value as  $13.55 \text{ F g}^{-1} \text{ at}\%^{-1}$ . For quinone group in 1 M  $\text{H}_2\text{SO}_4$ , it was  $27.09 \text{ F g}^{-1} \text{ at}\%^{-1}$ . For all RGO thin-film electrodes tested at the scan rate from 5 to  $500 \text{ mV s}^{-1}$ , averaged values of the specific pseudocapacitance per unit atomic percentage for carboxyl or phenol, carbonyl, and quinone groups were obtained as  $12.2 \pm 2.8$ ,  $12.8 \pm 2.5$ , and  $25.6 \pm 5 \text{ F g}^{-1} \text{ at}\%^{-1}$  respectively.

Figure. Specific pseudocapacitance per atomic percent of oxygen functional groups.

## 1. Introduction

Graphite fluoride is one of graphite intercalation compounds and used as lubricate and cathode material of primary battery. The graphite fluoride-lithium primary ((CF)<sub>n</sub>/Li) battery has been commercially used because of its high energy density, excellent discharge performance, and low self-discharge property. The battery reaction is shown as follows.

The cathode of the discharged (CF)<sub>n</sub>/Li battery is known to be the nano-composite of carbon and LiF<sup>1)</sup>. Several years ago, the author (S.S) found that the carbon product derived from the de-fluorination of graphite fluoride by charge-transfer complex such as lithium naphthalene has highly electrochemical capacitance regardless of its low microporosity<sup>2)</sup>. This suggests that the cathode discharge-product of (CF)<sub>n</sub>/Li battery can also work as active material of electrochemical capacitor. Thus, the authors revealed that the discharged (CF)<sub>n</sub>/Li battery can be re-charged as new hybrid electrochemical capacitor. In this paper, the authors announce the basic performance of the hybrid electrochemical capacitor using the discharged (CF)<sub>n</sub>/Li battery.

## 2. Experimental

Commercial graphite fluoride powder (Central Glass Co., Ltd., Japan) or Li foil (Honjo Metal Co., Ltd., Japan) was used as cathode or anode active material for (CF)<sub>n</sub>/Li battery, respectively. The sealed two-electrode cell for (CF)<sub>n</sub>/Li battery was constructed using these electrode materials, poly-propylene porous separator, and 1M LiPF<sub>6</sub>/ethylene carbonate and ethyl methyl carbonate electrolyte. The cell was discharged to lower cut-off voltage of 1V under galvanostatic condition (40 mA g<sup>-1</sup>) as the battery and then was re-charged/discharged between 2V and 4V as the capacitor.

## 3. Results and Discussion

The discharge-charge curves were shown in Fig.1. The first discharge-curve is the plateau around 2.5V, which is characteristic for the battery. The successive charge-discharge curves show the triangle shape, which means capacitive performance. This suggests that the carbon/LiF nano-composite as discharge-product of the cathode operates as the positive electrode of the capacitor and that the Li metal is electrochemically deposited / dissolved at the negative electrode. The authors term this new hybrid capacitor system as “Graphite-Fluoride Lithium Capacitor (GFLC)”. The GFLC indicates the higher energy density and power density than the EDLC and the performance is comparable to that of the Li-ion capacitor as shown in Fig.2.

Electrochemical capacitors are a subject of significant interest in the scientific community over the last few decades due to their outstanding features and perspective of use. They can be charged and discharged within seconds and operate up to million cycles. They may be also considered as environmentally-friendly devices when operating in neutral aqueous electrolyte, e.g.  $\text{Na}_2\text{SO}_4$ ,  $\text{Li}_2\text{SO}_4$ ,  $\text{KI}$ . However, carbon electrodes are conventionally bounded by fluorine-based polymers as polytetrafluoroethylene (PTFE) and polyvinylidenedifluoride (PVdF) which are highly hydrophobic, hence, limiting wettability of electrodes in aqueous electrolytes. Many efforts have been devoted to overcome this disadvantage and apply more sustainable materials as carbon electrodes binders. Use of cellulose has been recently reported and shown a great opportunity to consider biopolymers as useful substances in terms of carbon binding.<sup>1</sup> This work presents the application of another widely abundant biopolymer, chitin, as binder for carbon electrodes operating in aforementioned electrolytes.

Figure 1. Contact angle measurements of chitin-bounded electrode (left), and cyclic voltammograms ( $10 \text{ mV s}^{-1}$ ) for chitin- and PTFE- bounded electrodes (NORIT Supra 30) operating in 1M KI (right).

Chitin-bounded electrodes have shown promising performance, comparable to those bounded by PTFE. Cyclic voltammetry method confirmed good charge propagation across the electrode/electrolyte interface, presumably originating from improved electrode wettability. Moreover, galvanostatic charging/discharging measurements have indicated good capacitance retention while increasing current density. Application of chitin as a binder also results in limitation of activity of electrochemically generated iodine via trapping in biopolymer structure. Thus, chitin appears to be a cheap, environmentally sustainable alternative for fluoropolymers reflecting promising results and is being worth more-in-depth study.

# Ion Exchange Optimization of Polyaniline Films in Deep Eutectic Solvents for Supercapacitor Application

A. Robert Hillman, Karl S. Ryder, Abdulcabbar Yavuz  
Department of Chemistry, University of Leicester  
Leicester, LE1 7RH, UK  
ay54@le.ac.uk

Charge transfer and mass transport in energy storage devices can be improved by using nano-materials, which have greater surface area leading to an increase in power.<sup>1</sup> One suggestion is to design three-dimensional multifunctional nanoscale electrodes.<sup>2</sup> Polymer modified electrodes are intrinsically porous in nature and offer a large reactive surface area. This 3D reaction zone has the prospect of high species flux entering into the bulk of the polymer modified film, leading to an increase in the capacitance, which makes them suitable candidates for battery/supercapacitor devices. Most of the studies on supercapacitors focus on the deposition and cycling of the electrode material. However, the study of the electrolyte for supercapacitor applications has not received as much attention to date.

Here, the combination of novel Deep Eutectic Solvent (DES) electrolyte with polyaniline (PANI) modified electrodes, having conjugated backbones allowing for extensive delocalisation of electrons, is presented for supercapacitor application. In this study, significant attention is given to characterization of the fundamental electrochemical process during faradaic reaction of pseudocapacitance, complementing empirical study of the performance, stability and processability of supercapacitors.

There is abundant literature relating to conducting polymers in conventional liquid media where solvent transport is a very important part of film dynamics. In DES media, which are entirely composed of ions (consisting of a hydrogen bond donor (HBD) and a quaternary ammonium salt (QAS)), questions of solvent transfer do not occur. However, there is a much more complicated situation in terms of anion vs cation transfer. In particular, the anion used here is a complex anion ( $\text{Cl}^-$  with HBD). As the moving species is large, it may move too slowly in the context of supercapacitor. Therefore, cation movement may be preferred. Electrochemical (cyclic voltammetry) and acoustic wave (QCM) measurements were combined as an in-situ technique (EQCM) to study the motion of mobile species populations between DESs and PANI films. Since the ionic liquids are very viscous media that may affect film rigidity significantly, acoustic admittance measurement were used to obtain film ion population change data rigidly as a function of potential range, scan rate and scan numbers of deposition of PANI films, temperature and composition of DESs, and scan rate of redox switching of PANI in DESs.

Generally, thin PANI films ( $< 40 \text{ nmol cm}^{-2}$ ) have more cation dominated redox switching reaction. However, thick films have two significant characteristics depending on timescale. Normally, thinner films are more likely to have a surface control mechanism which is desirable for energy storage devices. However, the results showed that the rate limiting process does not just depend on film coverage but also depends on the growth conditions of the films; in particular the scan rate and potential window during polymerization could lead to different switching responses and performance of the resulting films. The HBD of the DES and temperature also affect the ion dynamics of PANI. A specific capacitance value of  $803 \text{ F g}^{-1}$  which is only 61% of the theoretical one was obtained from PANI cycling in Ethaline (a mixture of  $\text{Ch}^+\text{Cl}^-$  and ethylene glycol). The decreasing of specific capacitance of PANI is small with increasing scan rate indicating high power density of the materials. Excellent stability (more than 30 000 cycles) of PANI films in DESs was also demonstrated.

The next generation of electrical energy devices requires the combination of electrochemical storage systems with high power density and energy density. Electrochemical capacitors are known to have high power density and can be charged and discharged in seconds, up to millions of times [1]. However, they are characterised by low energy density. This drawback can be compensated for in a hybrid electrochemical system with a complementary electrode material that offers high energy density. Lithium manganese phosphate (LMP) is an inexpensive material that is capable of delivering a maximum energy density of  $\sim 700 \text{ Wh kg}^{-1}$ . Although it has low electrical conductivity, the lithium redox chemistry allows an operating voltage that is higher than electrochemical capacitors [1, 2]. In this research, we present for the first time, lithium manganese phosphate modified with gold nanoparticles (LMP/Au) as an electrode material for applications in lithium ion electrochemical capacitors. LMP was synthesized through a sol-gel synthetic route with subsequent calcination and coating with gold nanoparticles. The lithium ion electrochemical capacitor was prepared on a nickel foam substrate with carbon black to enhance the conductivity. All electrochemical measurements were carried out in 1 M  $\text{Li}_2\text{SO}_4$  electrolytic solution. The incorporation of gold nanoparticles to enhance the LMP is novel and preliminary findings show that the electrochemical performance of the LMP/Au nanocomposite is better than the unmodified LMP and this will be fully described during the conference.

Research on the more relevant factors governing the performance of carbons in electrochemical capacitors has been intensive over the past few years. Unfortunately, contradictory information has been obtained and there is still great controversy.

The study of a large variety of materials, including activated carbons, templated mesoporous carbons, carbon nanotubes, carbon fibers, carbon gels, carbide-derived carbons and graphene-type materials, shows that a systematic characterization is highly required to gain reliable insights into the different role of their properties in the electrochemical behaviour.

This approach illustrates that the total surface determined by standard adsorption of N<sub>2</sub> at 77 K may be misleading due to different reasons: i) it may be no longer available for the electrolyte ions. The existence of a distribution of pore sizes and/or constrictions at the entrance of the pores may hinder the access of the electrolyte to the overall porosity, ii) the filling of narrow cavities is a very slow process at 77 K and the equilibrium may not be achieved under the standard operation times. In such a case, the specific surface area determined by adsorption does not match the electrochemically active surface of the carbon and iii) some carbon materials suffer from a drop in their specific surface area upon fabrication of electrodes with features of the existing commercial devices. Therefore, the popular approach based on the specific surface area and the pore size of carbons to assess their suitability in electrochemical capacitors cannot be used in a straightforward manner.

It was found that carbons follow general patterns. Although the extent of the double layer has been identified as a key factor, other features, such as surface chemistry, electric conductivity, etc. also play a role. The corresponding impact is highly dependent on the electrolyte.

New correlations between structural and chemical characteristics of carbons and their performance allow evaluating the current challenges of nanocarbons in electrochemical capacitors.

The electric double layer is generally viewed as simply the boundary that interpolates between an electrolyte solution and a metal surface. Contrary to that view, molecular simulations show that the interface between ionic liquids and carbon electrode can exhibit structures and fluctuations that are not simple reflections of surrounding bulk materials. This rich behavior is absent from a mean-field picture that averages over intraplanar structure. The charge of the electrode is screened by the interfacial fluid and induces subtle changes in its structure, which cannot be captured by the conventional Gouy-Chapman theory. [1]

In recent years, we have performed molecular dynamics simulations on a variety of systems made of the 1-butyl-3-methylimidazolium hexafluorophosphate ionic liquid (either pure or mixed with acetonitrile) and a variety of carbon electrodes: planar graphite, carbide-derived carbons and nanoporous graphene. A key aspect of our simulations is to use a realistic model for the electrodes, by allowing the local charges on the carbon atoms to vary dynamically in response to the electrical potential caused by the ions and molecules in the electrolyte. [2]

These simulations have allowed us to gain strong insight on the structure and dynamics of ionic liquids at electrified interfaces. Even in the simpler case of planar surfaces, surprising ordering effects have been observed on a range of applied potentials [3]. Then, from the comparison between graphite and porous CDC electrodes, we have elucidated the molecular mechanism at the origin of the increase of the capacitance enhancement in nanoporous carbons [4,5]. The simulations also provide us the diffusion coefficients of the ions and the charging times for the full supercapacitor device. [6]

With evolution of functions, micro-electronic components demand more and more power. While the main battery of the whole device might fail to power everything, on-chip microsize power sources are required. Microbatteries suffer from low power performance owing to kinetic limit of intrinsic redox reactions [1]. Carbon based microsupercapacitors could be a solution for high power application thanks to energy storage by adsorption of electrolyte ions inside carbon porous network without kinetic limit [2]. Among all porous carbon materials, carbide derived carbons (CDCs) could be fabricated from chlorination of carbide, which is ceramic, enabling on-chip microfabrication process. Moreover, CDCs could offer high capacitance thanks to its tunable nanoporous network [3], making it perfect candidate for microsupercapacitors.

In this present work, we have successfully fabricated on-chip titanium carbide derived carbon (TiC-CDC) thin films by chlorination of PVD deposited TiC ceramic thin films on silicon wafer.

Figure 1 a) SEM photo of on-chip TiC-CDC thin film after chlorination (cross section); Voltammogram recorded at 20 mV/s in b) 1M H<sub>2</sub>SO<sub>4</sub> and c) 1M EMIBF<sub>4</sub> in acetonitrile (ACN).

The TiC-CDC thin film is uniform in thickness according to Figure 1a. Voltammograms of the material in both aqueous and organic electrolytes at 20 mV/s indicate capacitive behavior of chlorinated TiC-CDC thin film. 135 mF/cm<sup>2</sup> and 51.8 mF/cm<sup>2</sup> were achieved in 1M H<sub>2</sub>SO<sub>4</sub> aqueous electrolyte and 1M EMIBF<sub>4</sub> in ACN, respectively. Thus, nanoporous TiC-CDC thin films could be potentially applied as microsupercapacitors electrodes after patterning into interdigitated configuration.

# Surprisingly Large Improvements in SiC-CDC Based EDLC via Simple CO<sub>2</sub> Activation Method

Indrek Tallo, Ester Tee, Enn Lust, Thomas Thomberg, Heisi Kurig, Alar Jänes  
*Institute of Chemistry, University of Tartu*  
*14A Ravila Street, 50411 Tartu, Estonia*  
*indrek.tallo@ut.ee*

Silicon carbide derived carbon (SiC-CDC) is the cheapest and easiest to synthesize of all carbide derived carbon (CDC) materials. However, without using a prior templating method or additional modification, the intrinsic electrochemical properties of SiC-CDC are well below those of other CDC materials, such as TiC-CDC, WC-CDC or Mo<sub>2</sub>C-CDC. This can be attributed to the too narrow average pore sizes, which limit the mass transport inside the carbon particles. Although there are many activation methods for porous carbons available, which can increase the pore diameters, the CO<sub>2</sub> oxidation is one of the easiest. In this work nanoporous CDC were synthesized from SiC powders via gas phase chlorination within the temperature range from 1000 °C to 1100 °C. Thereafter the CDCs were additionally activated by CO<sub>2</sub> treatment method, resulting in nearly two-fold increase in specific surface area. The results of X-ray diffraction, high-resolution transmission electron microscopy and Raman spectroscopy showed that the synthesized CDC materials are mainly amorphous, however containing small graphitic crystallites, exposed mainly on surface regions of carbon powders. The low-temperature N<sub>2</sub> sorption experiments were performed and the specific surface areas, calculated according to Brunauer-Emmett-Teller theory, from 1100 m<sup>2</sup> g<sup>-1</sup> up to 2270 m<sup>2</sup> g<sup>-1</sup> were obtained, depending on the extent of CO<sub>2</sub> activation. The energy and power density characteristics of the supercapacitors based on 1 M (C<sub>2</sub>H<sub>5</sub>)<sub>3</sub>CH<sub>3</sub>NBF<sub>4</sub> solution in acetonitrile and SiC-CDC as an electrode material were investigated using the cyclic voltammetry, electrochemical impedance spectroscopy, galvanostatic charge/discharge and constant power discharge methods. The electrochemical data indicated huge increase in specific capacitance and thus, in energy density. Most importantly, the activation of SiC-CDC with CO<sub>2</sub> significantly improves (more than 40%) the performance (energy density, power density, etc.) of the supercapacitors especially at higher potential scan rates and at higher power loads [1].

The lithium ion capacitor (LIC) is a high energy hybrid system which combines an electrical double-layer (EDL) positive electrode made from nanoporous carbon with a negative graphite lithium intercalation electrode [1]. The electrolyte is a lithium salt which is generally dissolved in ethylene carbonate : dimethyl carbonate (EC:DMC) mixture. In the first concept of LIC, an auxiliary metallic lithium electrode has been used for graphite pre-lithiation. Latter, pre-lithiation has been proposed directly from the electrolyte [2] to circumvent the possible safety issues related with metallic lithium implementation, and also to simplify the device design. This leads to a decrease of electrolyte concentration and conductivity, which might have a negative impact on LIC power. Therefore, the most recent idea consists in irreversibly de-intercalating lithium from lithium metal oxide (lithium molybdenum oxide -  $\text{Li}_2\text{MoO}_3$  or lithium iron oxide -  $\text{Li}_5\text{FeO}_6$ ) incorporated in the positive activated carbon electrode [3]. However, in case of these oxides, the extraction potential of lithium ions exceeds 4.5 V vs. ref.  $\text{Li}/\text{Li}^+$ , which causes detrimental electrochemical oxidation of the electrolyte.

In this presentation, we investigated new materials (lithiated oxides and lithiated organic molecules) from which high amount of lithium can be irreversibly de-intercalated at potential lower than 4.5 V vs. ref.  $\text{Li}/\text{Li}^+$ . Figure 1a shows the evolution of electrodes and cell potentials during graphite lithiation at C/20. The reached capacity of  $360 \text{ mAh g}^{-1}$  indicates that the composition of the intercalation compound is close to the first stage  $\text{LiC}_6$ . The LIC cell demonstrated an excellent cycle life at different current loads from  $250 \text{ mA g}^{-1}$  to  $650 \text{ mA g}^{-1}$  in the potential range from 2.2 ~ 4.0 V (Figure 1b). The specific energy and power are close to  $50 \text{ Wh kg}^{-1}$ , and  $500 \text{ W kg}^{-1}$ , respectively (for comparison, the energy density of EDLC is  $3\text{-}10 \text{ Wh kg}^{-1}$  for EDLC, and the power density of lithium ion batteries is around  $300 \text{ W kg}^{-1}$  [4]).

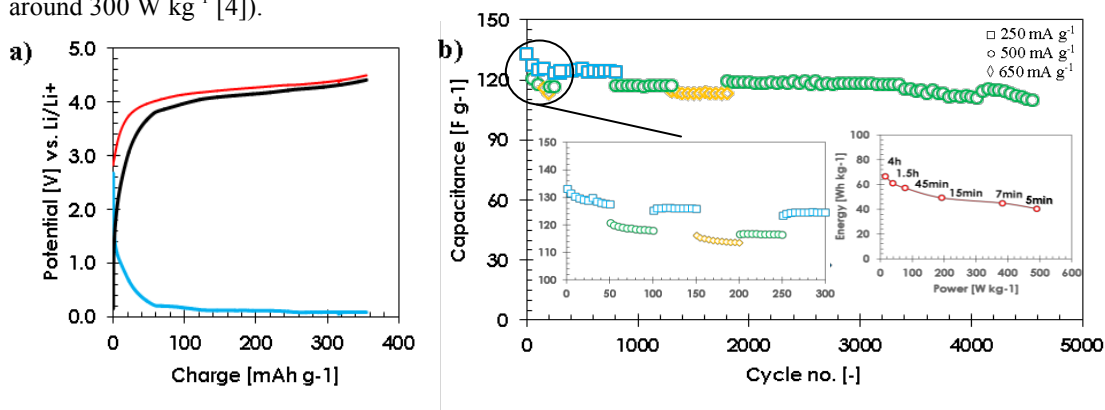

Fig 1. a) Evolution of electrodes and cell potentials during graphite pre-lithiation at C/20; b) Cycle life of the cell in the potential range 2.2 - 4.1 V with Ragone plot as inset. The electrolyte was  $1 \text{ mol L}^{-1}$   $\text{LiPF}_6$  in EC:DMC (vol. 1:1)

In the past decade, lot of attention has been put on electrochemical double layer capacitors (EDLCs), also known as supercapacitors, since they are one of the most promising electrochemical energy storage devices for high power delivery or energy harvesting applications. The charge storage mechanism in supercapacitor electrodes relies on electrostatic attraction between the electrolyte ions and the charges at the electrode surface, leading to a charge separation at the electrolyte/electrode interface.

During this presentation, we will show how the careful design of the carbon/electrolyte interface can help in designing high energy density carbons for supercapacitor applications. In a first step, by using Carbide-Derived Carbons (CDCs), we will show the control of the carbon porous structure impacts the capacitance of nanostructured carbons that sharply increases for pore sizes less than 1 nm. The combination of several techniques like in-situ NMR spectroscopy, EQCM and Molecular Dynamics simulations has then been used for studying the ion confinement effect in carbon nanopores and helped in developing our basic understanding of the electrolyte/carbon interactions in confined pores.

A last part of the presentation will be focused on some recent results on the development of micro-supercapacitors using bulk microporous carbon films. These micro-systems were prepared from the chlorination of sputtered bulk TiC films deposited onto Si wafer. Extremely high volumetric ( $500 \text{ F.cm}^{-3}$ ) and areal capacitance ( $> 150 \text{ mF.cm}^{-2}$ ) could be obtained, paving the way for the design of high energy micro-supercapacitors.

# Faradaic and Non-faradaic Interactions at the Electrode/Electrolyte Interface in Electrochemical Capacitors

Krzysztof Fic, Jakub Menzel, Elzbieta Frackowiak

*Poznan University of Technology, Institute of Chemistry and Technical Electrochemistry*

*Berdychowo 4, 60-965 Poznan*

*elzbieta.frackowiak@put.poznan.pl*

The mechanism of energy storage in electrochemical capacitors is quite well understood, however, there are still some issues related especially with carbon electrode ageing which need more in depth studies. It is widely accepted that ion transport within the carbon electrode bulk strongly depends on the porosity structure and interconnection of ions; presumably, there are some more specific criteria for effective ion transportation. It seems that some ions approach the interface easily and can be reversibly transported from/to electrolyte bulk, dependently on polarization applied. On the other hand, some ions – once interface is reached - tend to remain at the interface and cannot be reversibly desorbed. Such ‘memory effect’ of the electrode has rather negative influence on the supercapacitor cyclability and charging/discharging efficiency.

Our investigations performed for negative electrode have demonstrated that the voltage range of this electrode might be shifted towards hydrogen evolution potential and even easily exceeding this value. It is noteworthy that the interactions between the electrode and electroadsorbed hydrogen are the strongest in case of 6 mol/L KOH solution. Hydrogen stored *in statu nascendi* in the ultramicropores of the activated carbon keeps the potential of the electrode in deep cathodic region and allows reaching a higher voltage of the total system. More detailed investigations were focused on the influence of carbon microstructure on self-discharge of the electrode.

Typical oxidative working conditions of positive electrode resulted in a fast aggravation of the electrode material and significant capacitance fade in alkaline, neutral and acidic electrolyte, whatever type, especially for electrode with relatively high oxygen and micropore content. In order to avoid electrolyte decomposition and to improve electrode potential window, the electrolytes with redox activity (e.g. based on iodides, bromides) have been investigated. Results obtained suggest that redox activity of aforementioned species shifts the oxygen evolution potential towards higher value and prevents capacitance fade during cycling. The most recent studies suggest that electrolyte for positive electrode should retain the pH value during operation; in this case, the electrochemical response is sensitive for oxygen functionalities which might influence the pH value directly on the electrode/electrolyte interface.

This paper will report on electrochemical performance of various anions such as Cl, I, Br, SO<sub>4</sub>, NO<sub>3</sub> as well as cations of such metals as Li, Na, K, Cs, Mg, and Cu at electrode/electrolyte interface studied by various frequency-dependent methods such as electrochemical impedance spectroscopy and electrochemical quartz crystal microbalance (EQCM). Activated carbons with various type of porosity have been investigated in order to correlate porosity-related features with electrochemical parameters such as capacitance value, various type of resistance (ESR, EDR) and frequency response (mass change). Finally, aforementioned considerations will be discussed in direct regard of cyclability issues of carbon electrodes.

# Electrochemical Characterization of an Aqueous Hybrid Capacitor with Zinc and Activated Carbon Electrodes

## Introduction

Electric double layer capacitors (EDLCs) have attracted attention because of their high power density, long cycle life, etc. Aqueous electrolytes have advantages such as high ionic conductivity, low cost, incombustibility, low environmental load and so on, compared to organic electrolytes. However, the operating voltages of aqueous EDLCs are actually lower than the theoretical decomposition voltage of water, 1.23 V, leading to low energy and power densities. This is a serious issue of the aqueous EDLCs. Asymmetric capacitors or hybrid capacitors (HCs) composed of various faradaic electrodes and a non-faradaic activated carbon (AC) electrode have been investigated in order to increase the energy and power densities of EDLCs. It has been reported that HCs composed of an AC negative electrode and various oxide positive electrodes, realized the operating voltages over 1.23 V, leading to higher energy and power densities. On the other hand, there seems to be not so much researches about faradaic negative electrodes for aqueous HCs. We have assembled a new aqueous HC using Zn with large hydrogen overpotential as a negative electrode material and evaluated its electrochemical properties [1]. In the present study, we improved operating voltage of the aqueous HC with Zn and AC electrodes to realize higher energy and power densities.

## Experimental

An AC fiber cloth (GCI) was used as a positive electrode material of the present aqueous HC cell. The AC cloth was stuck on a glassy carbon plate with the carbon paste and heated at 100°C for 1 h to prepare an AC electrode. The AC electrode was impregnated with a (1 M  $\text{ZnCl}_2$  + 0.048 M HCl) solution as an electrolyte under a vacuum. An experimental HC cell was assembled using the AC and Zn sheet electrodes based on our previous paper [1]. The sulfonated-polypropylene separator was impregnated with the (1 M  $\text{ZnCl}_2$  + 0.048 M HCl) aqueous solution under a vacuum and stacked between the two electrodes. For comparison, an EDLC cell with two AC electrodes was also assembled. All charge-discharge cycling tests for the HC and EDLC cells were galvanostatically carried out at 2 mA. In all measurements temperature was kept at 30 °C.

## Results and Discussion

Figure 1 shows charge-discharge curves of positive and negative electrodes for the EDLC and HC cell as their operating voltage was changed between 0 and 2.0 V. With the present electrolyte, the EDLC cell could work well until the maximum operating voltage of 2 V. Fig. 1 shows the HC cell also worked well until the maximum operating voltage of 2 V, which was much higher than the previous aqueous HC with Zn negative electrode and alkaline electrolyte (1.4 V). In the HC cell, the potential of the Zn negative electrode was nearly constant because the following faradaic reaction reversibly occurred;  $\text{Zn} = \text{Zn}^{2+} + 2\text{e}^-$ . On the other hand, the potential of the AC positive electrode greatly changed during charge-discharge cycling. Specific capacitance was calculated from an average slope of the discharge curve for each cell, and the specific capacitance of the HC cell was much higher than that of the EDLC cell, so the increase in power and energy densities of the cell can be expected.

Fig. 1 Charge-discharge curves of both electrodes for EDLC and HC.

Supercapacitors are electrochemical energy storage devices ideally suited for high power applications; yet, their relatively low energy density is a limiting factor for many energy applications. Therefore, many current studies on supercapacitors are dedicated to explore strategies to increase the energy density while keeping the power density as high as possible. A highly promising approach employs aqueous electrolytes which enable the use of redox reactions either of the electrode material (e.g., surface functional groups or redox active metal oxides), or capitalize Faradaic reactions of the electrolyte itself. [1] The latter, or can be called as redox electrolyte hybrid capacitor, is a rather new approach which synergistically combines electrolyte systems related to redox batteries and electrodes known from supercapacitors. In contrast to conventional supercapacitors, this novel concept needs to ensure the physical separation of two different electrolyte reservoirs. This can be accomplished with ion exchange membranes (IEMs) which prevent redox active ions from crossing the membrane.

Up to the present, IEMs have been broadly investigated for redox flow batteries as the molecular dynamics in the presence of IEMs plays determining role in the performance of the redox flow battery system. On the contrary, only a few investigations have been carried out using IEMs in supercapacitor systems despite its growing importance on designing hybrid capacitors with redox active electrolytes. As a different behavior in the molecular dynamics is expected in the presence of IEMs for electric double layer (EDL) formation and redox reaction, a separate investigation of IEMs is required excluding redox reactive species. Here, we study the influence of IEMs in aqueous double layer capacitors in order to study separate effects of IEMs on the molecular dynamics in regards to double layer formation; and as a second part of the study, a redox electrolyte/double layer hybrid capacitor will be explored.

For the double layer capacitors, we investigated the electrochemical performance of an aqueous system (1 M Na<sub>2</sub>SO<sub>4</sub>) utilizing thin cation and anion exchange membranes (15-60 µm) and compare the results to a conventional porous polymer separator (namely, hydrophilic polytetrafluoroethylene). While the best rate performance was obtained from the porous separator retaining capacitances of about 88 % at a current density of 5 A/g, the thinnest IEM showed comparable capacitance retention of about 82 %.

In addition, we also present comparative first results applying a new type of redox electrolyte. We can show (Figure 1) that the use of thin IEMs allows not only increased capacitance gained from redox-active electrolyte but also high power performance as the ion diffusion for double layer formation is enhanced through shorter crossing-over distance for non-redox active ions.

We have been applying our original in-situ material processing technology called ‘Ultra-Centrifuging (UC) treatment’ to prepare a novel ultrafast nano-crystalline Li<sub>4</sub>Ti<sub>5</sub>O<sub>12</sub> (nc-LTO) /carbon nanofiber (CNF) composite electrode for the generation-II capacitive energy storage device of ‘Nanohybrid Capacitor (NHC)’ producing more than triple energy density of a conventional electrochemical capacitor [1]. Establishment of the LTO-NHC mass production technology is scheduled to 2017-2018 [2]. To further improve the energy density of the LTO-NHC, we have been pursuing LTO alternatives. Among different candidates, TiO<sub>2</sub> (B) possesses several advantages such as its 2-folds theoretical capacity (335 mAh g<sup>-1</sup>) of LTO (175 mAh g<sup>-1</sup>) and the comparable redox potential (1.6 V vs. Li/Li<sup>+</sup>). In addition, TiO<sub>2</sub>(B) is an industrially attractive material because of its inexpensive raw materials and its environmentally benign synthesis using only aqueous solution (e.g., water-soluble complexes) without any Li-sources [3]. Using the combination of UC treatment and hydrothermal treatment, nano-rectangular TiO<sub>2</sub>(B) (4-7 nm) has been successfully synthesized with the existence of nanocarbons (e.g., single-walled carbon nanotubes (SWCNT), multi-walled CNTs (MWCNT), and Ketjen Black (KB)). The use of four-nuclear Ti-complex [3] and the co-existence of nanocarbons during the synthesis simultaneously realized the minimized *b*-axis growth (4-5 nm, see Fig.1), the hyper dispersion of TiO<sub>2</sub>(B) nanoparticles, and the least contamination of TiO<sub>2</sub> impurities (anatase and rutile etc...). The integration of all these advantageous features endows the smooth and ultrafast Li<sup>+</sup> intercalation of TiO<sub>2</sub>(B) (236 mAh g<sup>-1</sup> at 300C in case of MWCNT, 1C = 335 mAh g<sup>-1</sup>) into A1 and A2 sites eliminating the plateau at undesirably high potential of 1.8-2.0 V vs. Li/Li<sup>+</sup>, which is often referred as TiO<sub>2</sub> anatase or TiO<sub>2</sub>(B) C1 site peaks [3]. The co-relation between the electrochemical performance and the quantified “dispersibility of TiO<sub>2</sub>(B) within TiO<sub>2</sub>(B)/nanocarbon composite” indicates that the UC-treated TiO<sub>2</sub>(B) composites possess ideal nano-entanglements of *b*-axis controlled TiO<sub>2</sub>(B) and nanocarbons, which can reconcile both of high loading of TiO<sub>2</sub>(B) (70-80 in weight) and the ultrafast electrochemical responses.

# Nitrogen-doped Mesoporous Carbon for Supercapacitor Application

Yong-Yao Xia, Yan-Fang Song and Dan-Dan Zhou

*Department of Chemistry, Institute of New Energy, Collaborative Innovation Centre of Chemistry for Energy Materials, Fudan University, Shanghai 200433, China. E-mail address: yyxia@fudan.edu.cn*

Compared with a wide pore distribution ranging from micropores (<2 nm) to macroporous and a random pore connection of activated carbon (AC), the highly ordered mesoporous carbons (OMCs) possess a quite narrow distribution in mesopore range and uniform pore connection, it shows much better electrochemical performances than conventional high-surface activated carbon at high current densities both in aqueous and nonaqueous electrolyte. Introducing nitrogen atom into the carbon framework plays an important role in the capacitance enhancement of OMCs due to the faradaic redox reactions by increasing of electron donor capability and improvement of electrode wettability. As for porous electrode, the surface area, pore size, pore distribution, pore structure, and morphology play important roles in the capacitive behaviors. In the present work, we will introduce several kinds of N-doped OMCs.

- (1) **Nitrogen-doped ordered mesoporous carbon (N-doped OMC) with a high surface area**[1]: A N-doped OMC was synthesized by using an organic–inorganic co-assembly method, in which resorcinol was used as the carbon precursor, dicyandiamide as the nitrogen precursor, silicate oligomers as the inorganic precursors, and F127 as the soft template. The N-doped OMC possesses a surface area as high as 1374 m<sup>2</sup>/g and a large pore size of 7.4 nm. It delivers a reversible specific capacitance as high as 308 F/g in 1 M H<sub>2</sub>SO<sub>4</sub> aqueous electrolyte, of which 58% of the capacity is due to pseudo-capacitance.
- (2) **Nitrogen-doped hierarchical mesoporous/microporous carbon (NMMC) derived from ordered carbide** [2]: NMMC was prepared by synthesizing nitrogen-doped mesoporous titanium-carbide/carbon composite, followed by in situ chlorination of carbides. The NMMC possesses a high surface area (1344 m<sup>2</sup>/g), large pore volumes (0.902 cm<sup>3</sup>/g), narrowed mesopore-size distributions (centered at 4.6 nm) and micropores drilled on the mesopore walls. The obtained carbon exhibits excellent performance with a reversible specific capacitance as high as 325 F/g in 1.0M H<sub>2</sub>SO<sub>4</sub> aqueous electrolytes contributed by the double-layer capacitance and pseudo-capacitance.
- (3) **Nitrogen-doped ordered mesoporous carbon nanofiber array (NOMCNFA)** [3]: A NOMCNFA was prepared by a combination of a hardtemplating and a soft-templating method. The obtained N-enriched carbon material has a high surface area (1030 m<sup>2</sup>/g) and a large pore volume (2.35 cm<sup>3</sup>/g), with uniform mesopores located at 15.0 nm. The material with a nitrogen content of 6.7 wt% shows a high capacitance of 264 F/g in 1.0M H<sub>2</sub>SO<sub>4</sub> electrolyte and a good rate capability with a capacitance retention of 86% at 10 A/g vs. 0.5 A/g. It also delivers an excellent cycling stability without capacitance fading over 10000 cycles.

*andrea.balducci@kit.edu*

In state of the art electrochemical double layer capacitors (EDLCs), activated carbons (AC) are used as electrode active materials, while solutions of tetraethylammonium tetrafluoroborate (Et<sub>4</sub>NBF<sub>4</sub>) in propylene carbonate (PC) or acetonitrile (AN) are used as electrolytes. These combinations of materials enable the realization of EDLCs with operative voltages of 2.7 to 2.8 V, extraordinary cycle life (>500.000 cycles), high power (up to 10 kW kg<sup>-1</sup>) and energy in the order of 5Whkg<sup>-1</sup>[1].

Many works indicated that an increase of the EDLCs energy would allow the introduction of these high power devices in a larger number of applications and, consequently, it would increase the market size of EDLCs [1-2]. Therefore, in the last years many efforts have been made to increase the energy of EDLCs.

The energy  $E$  stored in an EDLC system is described by the equation  $E=1/2 CV^2$ , where  $C$  is the capacitance and  $V$  the operative voltage of the device. Considering this equation, it is evident that to increase the operative voltage in the most convenient strategy to increase the energy of these devices. Consequently, the development of innovative electrolytes is a key aspect for the realization of high energy EDLCs: in the future new solvents, new conducting salts as well as new ionic liquids need to be considered.

In this work we report about the development of innovative conducting salts and about the use of computational screening for the identification of innovative solvents for EDLCs.

In the past only a relatively low number of studies focused on the development of new conducting salts for high voltage EDLCs. Nevertheless, the conducting salt play a key role on the double layer formation and, thus, on the energy and power of EDLCs. Recently we investigated the influence of conductive salts on the physical-chemical as well as electrochemical properties of PC based [2]. We showed that the operative voltage of EDLCs containing PC-based electrolytes can be increased by a mere change in conductive salt. However, anions and cations forming the conductive salt have to be carefully selected, as the choice of salt influences both electrochemical properties as well as ion transport properties of EDLC electrolytes, leading to an impact on energy and power storage in EDLC devices.

As mentioned above, the introduction of electrolyte materials that withstand higher operative voltages than state of the art systems can be considered a key-point for the realization of high energy, high cycle life EDLCs. To avoid time consuming “trial and error” experiments, it is desirable to “rationalize” this search for new materials. An important step in this direction is the systematic application of computational screening approaches. Taking this point into account, we tried to correlate results obtained via an innovative computational screening with the experimental results, in order to check, if the latter results are validating the prediction of the computation and therefore, if computation is a feasible tool for the determination of new electrolytes [3].

**Submitted to:** Novel Insights to Electrochemical Capacitors – 5<sup>th</sup> symposium

Electrochemical microsupercapacitors ( $\mu$ SC) is a key device to get autonomous smart microsystems [1, 2]. The performances of  $\mu$ SC are limited by the footprint area available for the micropower sources. To enhance the surface capacitance of a  $\mu$ SC, two strategies has been developed depending on electrodes material. For pseudocapacitive materials such as manganese dioxide ( $\text{MnO}_2$ ) or ruthenium dioxide ( $\text{RuO}_2$ ), the areal capacitance of the electrodes is improved by achieving a step-conformal deposition of thin film on high aspect ratio 3D scaffold. By combining electrodeposition and atomic layer deposition technologies, the surface capacitance of a pseudocapacitive thin film is significantly improved by the Area Enlargement Factor (AEF) of the 3D topology [3]. The capacitance of a 250 nm thick  $\text{MnO}_2$  thin film moves from 11  $\text{mF}/\text{cm}^2$  (2D topology) up to 700  $\text{mF}/\text{cm}^2$  when the deposition is achieved on 3D silicon micropillars (75  $\mu\text{m}$  depth). Interesting results obtained on 3D interdigitated symmetrical full device will be presented in aqueous (0.5M  $\text{Na}_2\text{SO}_4$ ) and ionic liquid electrolytes. Collective fabrication on a 3 inch silicon wafer will be reported. For carbon based  $\mu$ SC, carbon derived carbide (CDC) material is a suitable candidate to fabricate on chip  $\mu$ SC at the wafer level [4, 5]. Titanium carbide has been sputtered on a 3 inch silicon wafer. The surface capacitance of the  $\mu$ SC directly depends on the film thickness. The sputtering parameters has been tuned to reach a low stress and highly conductive metal carbide material (up to 12.5  $\mu\text{m}$  thick). Inductively Coupled Plasma / Reactive Ion Etching technology is used to fabricate on chip interdigitated planar TiC electrodes. The resulting interdigitated electrodes are chlorinated at 450  $^\circ\text{C}$  under  $\text{Cl}_2$  to fabricate CDC based  $\mu$ SC at the wafer level.  $\mu$ SC performances will also be presented in aqueous (1M  $\text{H}_2\text{SO}_4$ ) and organic electrolyte (1M EMIBF<sub>4</sub>/AN).

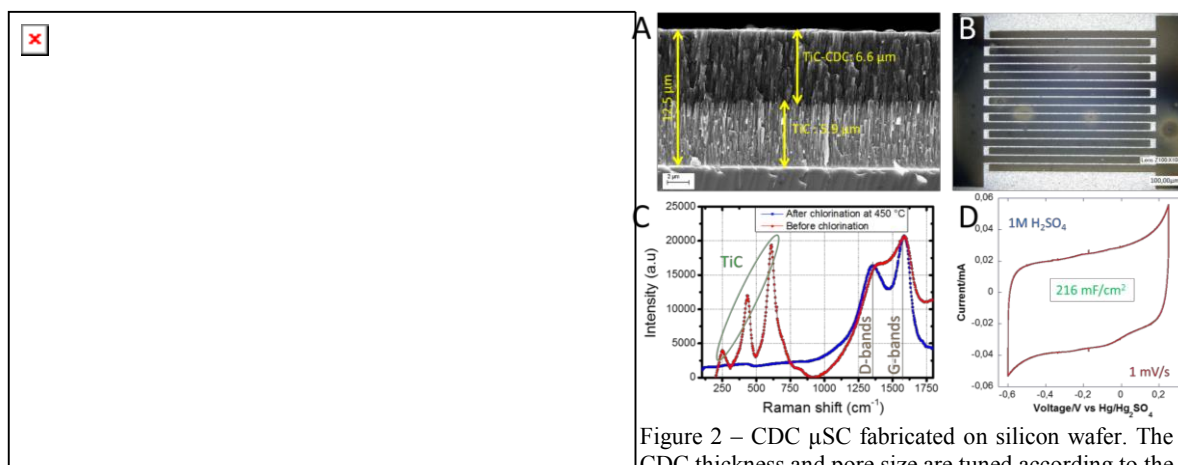

Figure 2 – CDC  $\mu$ SC fabricated on silicon wafer. The CDC thickness and pore size are tuned according to the chlorination parameters. The capacitance of CDC single electrode reaches 216  $\text{mF}/\text{cm}^2$  (6.6  $\mu\text{m}$  thick).

# Combination of Li-salt-based electrolytes with activated carbon electrodes for the development of hybrid battery-supercapacitors

S. Dsoke, T. Zhang, B. Fuchs, M. Secchiaroli, S. Kaymaksiz and M. Wohlfahrt-Mehrens  
Zentrum für Sonnenenergie- und Wasserstoff-Forschung Baden-Württemberg  
Helmholtzstrasse 8, D-89081 Ulm, Germany  
sonia.dsoke@zsw-bw.de

Hybrid battery-supercapacitors are high energy/high power devices obtained through the combination of high energy materials, normally employed in Li-ion Batteries (LIBs), and high power carbonaceous materials, used in Electrochemical Double Layer Capacitors (EDLCs) [1]. Various hybridization approaches can be used in order to realize such devices. In one of these hybridizations anode and cathode are composite electrodes containing both Li-insertion and carbonaceous materials internally [1]. A broad variety of Li-salt-based organic electrolytes have been used in these devices [1-3]. However, these electrolytes are developed for pure Li-batteries materials but not for capacitor materials. This work investigates the interactions among several Li-salt-based organic electrolytes and pure activated carbon (AC) electrodes. Important condition is that the system is stable at the working potential of the Li-insertion materials. Fig. 1 reports the electrochemical stability window (ESW) of one of the most used commercial electrolyte (1M LiPF<sub>6</sub> in EC:DMC) and of other electrolyte formulations developed by our group. Unfortunately, the commercial electrolyte starts to decompose at the voltage where Li<sub>4</sub>Ti<sub>5</sub>O<sub>12</sub> (LTO) works. It was found that the cathodic stability window can be improved by properly modulating solvent and salt compositions in the electrolyte. This study contributes to develop high performance and stables hybrid-battery supercapacitors.

**Fig.1** – Electrochemical stability window of a commercial electrolyte (1M LiPF<sub>6</sub> in EC:DMC) and of three new electrolyte formulations with AC-based electrodes. The red arrows indicate the working voltage of some of the Li-insertion materials normally employed in hybrid battery-supercapacitors.

R. China. E-mail: [george.chen@nottingham.ac.uk](mailto:george.chen@nottingham.ac.uk)*

As a classic topic in research and development, electrochemical energy storage (EES) is gaining unprecedented fast growing academic and industrial interests in recent years, thanks at least partly to the great success in material and device innovations and commercialization of lithium ion batteries and carbon based supercapacitors. In terms of storage and discharge performance, lithium ion and other rechargeable batteries are commonly perceived to be the champion in terms of high energy density or specific energy, whilst supercapacitors are known for their fast charging-discharging capability and long cycle life. However, there has always been the technological and commercial desires to make batteries as fast as supercapacitors, or supercapacitors with the high capacity of batteries. To achieve this goal, various new concepts have been coined and demonstrated in laboratory, such as lithium ion capacitor, sodium ion capacitor, redox electrolyte supercapacitor, supercabattery and supercapattery [1-4].

In terms of electrochemistry, a charging or discharging process (CDP) at the electrode level could be physical or chemical, or both. The physical electrode CDP is well understood to be associated with the electrical double layer and it is **capacitive** in nature, i.e. the current-potential relation is the same as that of a capacitor. For a chemical electrode CDP, reactions take place involving electron transfer (ET) at the interface between the electrode and the electrolyte, or between the current collector and the active material on the electrode. Many reversible or quasi-reversible ET reactions at the electrode | electrolyte interface can be described by the Nernst Equation, and this **Nernstian mechanism** is the basis of the redox electrolyte supercapacitor [2,3]. The Nernstian behaviour can also be seen in some ET reactions at the “current collector” | “active material” interface such as those in batteries. However, in many other cases, ET reactions occurring at the “current collector” | “active material” interface involve electrons in the delocalized bands of the active material. Such processes would follow the **capacitive mechanism** and are well represented by pseudo-capacitance [4]. Combining the Nernstian and capacitive mechanisms into one device for charge storage is the common strategy in all the new concepts mentioned above, but such a combination requires theoretical and technological reconsideration. For example, the four cyclic voltammograms (CVs) in **Fig. 1** are all evidence of reversible or quasi-reversible CDP on electrode, but only the rectangular CV in (c) can be used for derivation of capacitance. This presentation will offer more explanations and discussions with several examples from the literature and the author’s own laboratory.

**Fig. 1.** Schematic illustration of cyclic voltammograms of (a) reversible, and (b) quasi-reversible Nernstian CDPs, (c) capacitive CDP, and (d) combined Nernstian and capacitive CDP.

# Design and Modification of Inorganic/Organic Polyoxometalates-Carbon Pseudocapacitive Electrodes

Keryn Lian, Matthew Genovese and Yeewei Foong  
Department of Materials Science and Engineering  
University of Toronto, Toronto Ont. Canada  
Keryn.lian@utoronto.ca

Multi-walled carbon nanotube (MWCNT) electrodes modified with mixtures of polyoxometalates (POMs) were investigated for electrochemical capacitor (EC) applications. Although different POMs, e.g.  $\text{PMo}_{12}\text{O}_{40}^{3-}$  ( $\text{PMo}_{12}$ ) and  $\text{PW}_{12}\text{O}_{40}^{3-}$  ( $\text{PW}_{12}$ ), have their own characteristic electrochemical activity windows, they showed very unique electrochemical behavior when these POM ions are combined in solution. The resulting electrochemical behavior as reflected in cyclic voltammograms are very different from the individual POM ions. Further analyses revealed that the POM ions do not just mix physically, but instead react to form  $\text{PMo}_{12-x}\text{W}_x$  mixed addenda chemistries. By simply mixing  $\text{PMo}_{12}$  and  $\text{PW}_{12}$  in different ratios, a variety of mixed addenda ions, each with unique electrochemical properties, can be readily synthesized.

Leveraging this novel mixed addenda synthesis, unique POM redox behavior can be captured using layer-by-layer (LbL) deposition on CNT to design molecular coatings that demonstrate desired pseudocapacitive characteristics. The best performance was achieved with a coating that superimposed a 3:1  $\text{PMo}_{12}\text{O}_{40}^{3-}$ - $\text{PW}_{12}\text{O}_{40}^{3-}$  mixed layer on a 1:1  $\text{GeMo}_{12}\text{O}_{40}^{4-}$ - $\text{SiMo}_{12}\text{O}_{40}^{4-}$  mixed layer (Fig.1), which resulted in an 11X capacitance enhancement over bare CNT. This dual layer electrode also demonstrated a close to rectangular CV profile attributed to the overlapping redox features of the POM combination. The design of custom POM coatings to engineer the electrode surface represents a promising strategy for the development of high performance pseudocapacitive electrodes. In this talk, we will discuss several different POM mixtures, their electrochemical behavior, the mechanisms of mixed addenda POM formation, and the effects of their multilayer superimposed combination on MWCNT.

Fig. 1 Cyclic Voltammograms of the bare CNT (gray), the 3:1  $\text{PMo}_{12}\text{O}_{40}^{3-}$ - $\text{PW}_{12}\text{O}_{40}^{3-}$  mixed layer on CNT (blue dashed line), the 1:1  $\text{GeMo}_{12}\text{O}_{40}^{4-}$ - $\text{SiMo}_{12}\text{O}_{40}^{4-}$  mixed layer on CNT (red) and the combined 3:1  $\text{PMo}_{12}\text{O}_{40}^{3-}$ - $\text{PW}_{12}\text{O}_{40}^{3-}$  / 1:1  $\text{GeMo}_{12}\text{O}_{40}^{4-}$ - $\text{SiMo}_{12}\text{O}_{40}^{4-}$  dual layer on CNT (black).

# Valuing Electrochemical Capacitor Technology

The value of energy storage, when added to a power system, depends strongly on operating details. Moreover, value can be realized in a variety of ways, for instance by reducing the initial system cost, its operating cost, or its life-cycle costs; enhancing system power performance; increasing system operating efficiency; lowering maintenance requirements; or improving overall system reliability (1). A priori quantification of this value is often possible for systems having known (or at least correctly assumed) operating modes, which then permits comparisons to be made between systems without and with energy storage of various types and amounts.

Electrochemical capacitor (EC) technology (sometimes referred to by the product names Supercapacitor or Ultracapacitor) has several unique characteristics compared with the many different types of reversible energy storage. In general, ECs have a characteristic response time of about one second (time for a full discharge or a full charge), can cycle more than one-million times with minimal performance fade, and will operate with extraordinarily high reliability. On the negative side, ECs generally have more than 100-times higher initial cost than other popular energy storage technologies. Even at such costs, ECs are overwhelming selected as the storage technology of choice in certain applications because of the value they bestow.

This presentation focuses on the value that can be provided by adding energy storage to a power system. Several important applications are examined to quantify the value offered by EC technology compared with a no-storage system and with systems using other storage technologies. A goal is to convincingly demonstrate that characteristics other than energy/mass are important and in fact largely responsible for the rapid annual world-wide growth rate of electrochemical capacitor energy storage technology.

# On the Performance and Self-Discharge of a Redox-Active Electrolyte Supercapacitor Based on an Ionic Liquid Modified with Ferrocene

Dominic Rochefort, Han Jin Xie, Bruno Gelinas  
Chemistry Department, Université de Montréal  
CP6128 Succ. Centre-Ville, Montréal, Qc CANADA H3C3J7  
dominic.rochefort@umontreal.ca

Energy storage in carbon-based electrochemical capacitors is mainly achieved via the formation of the electric double-layer at the electrode-electrolyte interface. Non-faradaic charge storage allows reaching high power levels for prolonged cycling but the energy density remains limited to the extent of active surface area accessible to the ions composing the electrolyte. Increasing the energy of carbon-based electrodes can be achieved by modifying their surface with grafted electroactive centers to add a faradaic contribution to the charge storage. Another strategy to increase energy via faradaic reactions and which has been the subject of an increased interest over the last 2 or 3 years, is to dissolve an electroactive molecule in the electrolyte. The electroactive species can either be added to the solvent in the presence of the supporting electrolyte (redox additive electrolyte) or the supporting electrolyte may also be the electroactive species in redox-active electrolyte supercapacitors (RESCs).[1, 2] While these systems may be appealing due to their simplicity and the potentially higher energy densities offered, it is still difficult to predict if they will make it into real devices or remain within the walls of academic labs. Indeed, more developments and studies will be necessary to clearly define the metrics of charge storage, to increase cell voltage and to prevent self-discharge in RESCs.[3, 4] to name only a few of the issues they are facing currently. This research will focus on these two last issues.

This contribution discusses on the use of an electroactive ionic liquid as the electrolyte in a RESC based on activated carbon electrodes. The electroactive ionic, presented in Figure 1, uses an alkyylimidazolium cation with a new type of anion obtained from the modification of the bis(trifluoromethylsulfonyl)imide (Tf<sub>2</sub>N) anion with ferrocene.[5]

Figure 1. Structure of the alkyylimidazolium ferrocenylsulfonyle(trifluoro-methylsulfonyl)imide (FcTfN) electroactive ionic liquid.

Figure 2. SEM image of the film formed at the positive electrode from the deposition of the oxidized FcTfN anion.

The electrochemistry of these alkyylimidazolium-FcTfN ionic liquids, either pure or diluted with acetonitrile in symmetrical cells made of Black Pearls 2000 activated carbon electrodes was investigated by cyclic voltammetry and galvanostatic charge-discharge experiments. The RESC could be operated at a maximum voltage of 2.5 V and provided a 126 % increase in capacitance compared to the same device with a non-electroactive ionic liquid (EMIm Tf<sub>2</sub>N). The evaluation of increase in energy storage will be discussed in terms of capacitance and energy density. We found that at high concentrations in electroactive ionic liquid, the self-discharge was significantly hindered due to the deposition of the oxidized anion on the electrode surface (Figure 2). This film was dissolved into the electrolyte following the reduction of the ferrocenium-TfN zwitterion back to the ferrocene-TfN anion. This way of suppressing self-discharge without semi-permeable membranes is advantageous to avoid increasing complexity, cost, volume and weight of the device.

Thanks to its remarkable physical and morphological properties, graphene has been considered as potential electrode material for supercapacitors. Attractive performances were expected, especially because of its high electronic conductivity and large theoretical developed surface area. Beside a few exceptions, most of the studies in the field report on specific capacitances in the same range as for electrode materials based on activated carbon, typically about 100 to 150 F/g. These limitations have been assigned to material restacking, structural defects, and complex surface chemistry controlling both active surface area and electrode conductivity. To address these performance limitations, we have explored two different approaches. The first one is on the synthesis of graphene-like carbide derived carbons produced by chlorination of SiC nanosheets obtained by the magnesio-thermal reduction of a silica/graphene oxide nanocomposite. The resulting microporosity in the graphene sheets is shown to strongly improve the rate capability of the electrode material [1]. The second approach is on the decoration of the open surface of graphene layers by pseudocapacitive materials, including  $\text{Fe}_3\text{O}_4$  and  $\text{MnO}_2$  [2,3]. The resulting nanocomposite materials show attractive power capability thanks to the electronic conductivity of graphene while the pseudocapacitive metal oxides strongly contribute to the energy density.

Research efforts in electrochemical double layer capacitors (EDLCs) are currently focused on the enhancement of the energy density which relies on the electrode active material and electrolyte nature. As a matter of fact, a large number of publications is dedicated to the development of carbon based materials with optimized characteristics, including enhanced electronic conductivity, high surface area and optimized porous structure. The pore size distribution, inherited from the carbon precursor structure as well as synthetic conditions, appears to be critical, especially in the micro/meso pore range. Alternatively, the effect of doping with metals and/or hetero-elements is also thoroughly investigated.

In the present work, we have studied the electrochemical behavior of novel electrode materials based on porous carbons derived from the pyrolysis of so-called sacrificial metal-organic frameworks (MOFs) pyrolysis. The richness of the MOF chemistry suggests some attractive opportunities for the control of the pore size distribution as well as metal and nitrogen doping levels in the resulting carbons.

In a first step, an imidazolate Zn-based MOF, ZIF 8 (Fig.1, left), was selected. Such a ZIF 8 material has recently been used as a precursor to synthesize a Fe-N-C catalyst with unprecedented activity and power performance in fuel cell applications owing to the high microporous area and pore accessibility of its carbon substrate [1]. In the present study, this MOF precursor led to a series of carbon materials with large surface areas and tailored pore size distributions thanks to controlled synthetic conditions. Here, we report on the supercapacitive behavior of these MOF-derived carbons with various Cr doping levels.

In a second step, the MOF precursor was changed to ZIF 61 (Fig.1, right) and the impact of the resulting pore structure on the capacitive behavior of the corresponding electrode material was investigated.

The storage performances and mechanisms of these various electrode materials are discussed. This investigation opens the way for the use of tailored MOF-derived carbons as innovative electrode materials for supercapacitors.

Fig. 1. The single crystal x-ray structures of ZIF-8 (left) [2] and ZIF-61 (right) [3]. For each, the network is shown as a stick diagram (left) and as a tiling (center). (Right) The largest cage in each ZIF is shown with ZnN<sub>4</sub> tetrahedra in blue H atoms are omitted for clarity.

olivier.crosnier@univ-nantes.fr

The volumetric capacitance of supercapacitors is one of the limiting factors of today's stationary applications. New materials with improved storage properties are necessary to meet the requirements concerning high-performance energy storage devices while considering a reasonable manufacturing cost and a low environmental impact<sup>1,2</sup>. Moreover, not only the specific capacitance, but also the volumetric properties play a key role, especially for stationary applications. In order to meet those requirements, our interest has focused on high-density oxides operating in aqueous electrolytes.

Metal tungstates (M<sup>2+</sup>WO<sub>4</sub>) represent an important group of inorganic high-density oxides with excellent functional and electronic properties<sup>3</sup>. Iron tungstate (FeWO<sub>4</sub>), crystallizes in the wolframite-type structure, characterized by distorted [MO<sub>6</sub>] and [WO<sub>6</sub>] octahedra, and has recently been studied in lithium-ion batteries<sup>4</sup>. FeWO<sub>4</sub> has been synthesized *via* various low-temperature methods (polyol-mediated<sup>5</sup>, hydrothermal<sup>6</sup> synthesis...) in order to obtain high specific surface area nanoparticles which have been characterized by XRD, TEM (Figure 1) and electrochemically tested as supercapacitor electrode materials in a 5M LiNO<sub>3</sub> aqueous electrolyte at 20 mV/s (Figure 2). The material exhibits very promising properties and *in operando* Mössbauer spectroscopy experiments, performed in a specially designed cell, have revealed that the Fe<sup>2+</sup>/Fe<sup>3+</sup> surface redox reactions are clearly involved in the storage mechanism. The synthesis conditions, materials characterizations and electrochemical performance will be detailed in the presentation.

# Micro-Supercapacitors Based on Carbon Hybrid Fibers

Yuan Chen

*School of Chemical and Biomedical Engineering, Nanyang Technological University, Singapore  
N1.2-B1-16, 62 Nanyang Drive, Singapore 637459  
chenyuan@ntu.edu.sg*

Micro-supercapacitors are promising energy storage devices for miniaturized portable electronics. Their main limitation, however, is the low volumetric energy density. We produced hybrid carbon fibers using the capillary chromatography column as a one-dimensional hydrothermal micro-reactor, in which reduced graphene oxide (rGO) and single-walled carbon nanotubes (SWCNTs) self-assembled into an interconnected SWCNT network with rGO sheets interposed along the microfiber axis to create a mesoporous microstructure of a large surface area ( $396 \text{ m}^2/\text{g}$ ) and a high electrical conductivity ( $102 \text{ S/cm}$ ). The resultant fiber showed capacity of  $300 \text{ F/cm}^3$ . The fiber micro-supercapacitors exhibited a high volumetric energy density of  $\sim 6.3 \text{ mWh/cm}^3$ .<sup>1</sup>

Furthermore, the all-carbon hybrid fibers can be controllably functionalized to yield versatile composite fibers with either capacitive or Faradic characteristics. By matching the specific capacitances of one  $\text{MnO}_2$ -coated rGO/SWCNT fiber as battery-type (positive) electrode and the other N-doped rGO/SWCNT fiber as capacitor-type (negative) electrode, we constructed fiber-based asymmetric micro-supercapacitors with a voltage window of  $1.8 \text{ V}$  and excellent cycling stability.<sup>2</sup>

These results demonstrate the great potentials of graphene and carbon nanotubes in building fiber supercapacitors as miniaturized energy storage devices.<sup>3</sup>

# Preparation and characterization of Mn oxide-based composites for high-performance asymmetric supercapacitors

Chi-Chang Hu, Arturas Adomkevicius, Shin-Ming Li, Tzu-Man Ou  
Department of Chemical Engineering, National Tsing Hua University  
101, Sec. 2, Kuang-Fu Rd., Hsin-Chu city, 30013 Taiwan  
cchu@che.nthu.edu.tw

Recently, a lot of investigations focus on extending the cell voltage in order to enlarge the specific energy of asymmetric supercapacitors (ASCs). Here, we proposed two routes for preparing Mn oxide-based composites with ideal pseudocapacitive characteristics to demonstrate the material design concept for ASCs [1,2].

A 3D reduced graphene oxide/carbon nanotube (rGO/CNT) structure with a good wetting property, high porosity, and large surface area is homogeneously deposited with amorphous manganese oxide (a-MnO<sub>x</sub>) by CV deposition. The flowery a-MnO<sub>x</sub> structure with slender petals (ca. 5-8 nm) on the framework of hierarchically porous rGO/CNT matrix not only enables full utilization of a-MnO<sub>x</sub> but also retains sufficient conductivity and porosity for the high-rate charge-discharge application. The use of a-MnO<sub>x</sub> on the 3D rGO/CNT material produces high specific capacitance of MnO<sub>x</sub> (ca. 1200 F/g) which is much higher than that of a-MnO<sub>x</sub> ( $C_{S,Mn} = 233$  F/g). The specific energy and specific power of a-MnO<sub>x</sub>/rGO/CNT (single electrode) are respectively as high as 46.2 Wh/kg and 33.2 kW/kg.

Sodium pre-doped manganese oxide is prepared via a simple synthesis method for the ASC application. The pre-doping quantity of sodium significantly affects the crystallite size and morphology of resultant oxide nanoparticles, leading to the variation in capacitive performances. An aqueous ASC with a cell voltage of 2.4 V is demonstrated using activated carbon as the negative electrode and Na-doped Mn oxide/carbon as the positive electrode. The specific energy and power of this ASC (based on total mass of active materials) measured at 20 A g<sup>-1</sup> are equal to 22.72 Wh/kg and 24.41 kW/kg, respectively.

Fig. 1 Cyclic voltammograms of (1) MnO<sub>2</sub>, (2) Na-doped MnO<sub>2</sub>-10, (3) Na-doped MnO<sub>2</sub>-15, and (4) Na-doped MnO<sub>2</sub>-20 in 0.5 M Na<sub>2</sub>SO<sub>4</sub> at 25 mV s<sup>-1</sup>.

# Structure and Capacity of a Tin-Copper-CNT Composite Anode and its Lithium Ion Hybrid Capacitor Performance

Dah-Shyang Tsai, Wei-Wen Chiang, Chung-Lun Hsieh

Department of Chemical Engineering, National Taiwan University of Science and Technology

43, Keelung Road, Section 4, Taipei, Taiwan 10607

e-mail address: dstsai@mail.ntust.edu.tw

We have fabricated the lithium ion capacitor with tin-copper-CNT composite anode and activated carbon cathode, and found attributes worthy of further investigation. This report aims to study preparation and structure details of the tin-copper-CNT composite anode, which is critical to the capacitor performance.

The anode composite has been prepared with electrodeless deposition of tin and copper on the slightly oxidized CNT bundle and lithiation down to 0.08 V (vs.  $\text{Li/Li}^+$ ). The prelithiation step makes tin and copper sufficient alloyed with lithium and builds a proper layer of solid electrolyte interface (SEI), so that the anode may exhibit large and sufficiently steady capacity.

Figure 1(a) shows the outside diameter of the multi-walled CNT raw material is  $\sim 10\text{-}30$  nm. After coating of tin and copper, the CNT diameter grows and roughens because of the attached metal layer, as illustrated in Figure 1(b). Figure 1(c) indicates that prelithiation in a half cell increases the tube diameter further, also cut the tube short. The charge and discharge curves of Sn/Cu/CNT electrode at  $0.1\text{ A g}^{-1}$  are plotted in Figure 2(a), when the electrode was prelithiated between 2.0 and 0.08 V (vs.  $\text{Li/Li}^+$ ). The first cycle displays a large capacity of significant irreversibility,  $\sim 1600\text{ mAh g}^{-1}$ , because of SEI buildup. The capacity of the second and third cycle is much less,  $\sim 600\text{ mAh g}^{-1}$ , which is the cycle capacity. When the lithiated Sn/Cu/CNT anode is assembled with an activated carbon electrode with a mass ratio 1:1.5, the hybrid capacitor demonstrates a large amount of energy capacity, as illustrated in Figure 2(c). At low current, the energy density can reach  $90\text{ Wh kg}^{-1}$  when the voltage window is set 3.8 V. Figure 2(b) presents the electrode potential variations during charge and discharge at low current  $0.1\text{ A g}^{-1}$  and window 3.8 V. The charge/discharge curves are near triangular shape.

\*kbkim@yonsei.ac.kr

Supercapacitors are attracting much attention for use in high power energy storage devices. Electrode materials for supercapacitors are carbon-based materials such as activated carbon, carbon nanotubes, graphene and their composite. Among them, activated carbon is the most widely used electrode materials in commercial supercapacitors due to their reasonable cost and scalable production.<sup>1</sup>

Recently, graphene, a one-atom thick two-dimensional honeycomb carbon nanostructure, has been investigated as an electrode material for supercapacitors, owing to its high surface area ( $2630 \text{ m}^2\text{g}^{-1}$ ), sufficient porosity, superior conductivity ( $10^4 \text{ Scm}^{-1}$ ), and excellent mechanical stability.<sup>2</sup> However, one particular issue with graphene is its tendency to aggregate due to strong intersheet adhesion by van der Waals attraction. Restacking of sheets not only reduces its specific surface area, but also compromises their electrochemical properties. Therefore, strategies for preventing graphene aggregation have been studied, which typically include introducing spacer in-between graphene layers, such as carbon black,<sup>3</sup> carbon nanotubes,<sup>4</sup> metal oxide,<sup>5</sup> and conducting polymer<sup>6</sup>, functionalizing graphene sheets to develop wrinkle on graphene surface,<sup>7</sup> and developing three-dimensional architectures by hard template method or graphene self-assembly.<sup>8</sup>

Unlike two-dimensional graphene sheets, the three-dimensional graphene structure assembled with two-dimensional graphene sheets have high free volume and excellent compressive properties, and can tightly pack without significantly reducing the accessible surface area.<sup>9</sup>

In this study, we report a novel strategy for fabrication of graphene micro-sphere by spray-drying method using ionic liquid as a nanospacer between graphene sheets. More details on the fabrication procedure, electrochemical and structural properties will be presented at the meeting.

Electrical double layer capacitors (EDLCs), or supercapacitors hold an important position among all the energy storage systems owing to their high power capabilities. Nowadays, the main challenge for supercapacitors is to increase their energy density without sacrificing their high power nature. Aside from the development of novel constituent materials (electrode, electrolytes, etc.), obtaining a fundamental understanding of the charge storage mechanism at molecular scale also holds the key for future design of supercapacitors.[1] Recently, it has been reported that Electrochemical Quartz Crystal Microbalance (EQCM) technique can serve as a gravimetric probe to study the concentration and compositional changes in porous carbon.[2] Therefore, it can be a powerful tool for studying the in-situ ion transport and the solvation effect during charging in the confined carbon micropores.

In the first part of this work, carbide-derived carbon (CDC) with two different average pore sizes (1 and 0.65 nm) were tested in neat and acetonitrile (AN)-solvated ionic liquid (EMI-TFSI). Ion adsorption during charging in these systems was characterized by in-situ EQCM and cyclic voltammetry (CV) measurements. Results have shown that different charge storage mechanisms are involved for positive and negative polarization. Experimental acetonitrile solvation numbers were estimated for EMI<sup>+</sup> cation, and partial desolvation was observed when decreasing the carbon pore size from 1 down to 0.65 nm. In the second part, in-situ NMR [3] was coupled with in-situ EQCM for investigating the same electrode/electrolyte system (YP-50F in  $\text{P}(\text{Tf}_2\text{B})_4/\text{AN}$ ) by potentiostatic measurements. Thanks to the quantitative nature of NMR, the amount of cation and anion at different charge states could be determined, and different charging mechanisms have been found for different electrode polarizations. In-situ EQCM results agree well with NMR results, and offer important information on ion solvation inside the micropores. The combination of these two in-situ techniques brings important insights on the charge storage mechanisms and the EDL structure upon charging.

**Figure 1:** Scheme of ion transport in 1-nm pores during different charging states (taking neat EMI-TFSI as example)

# Influences of Residual Water in Porous Carbon Electrodes on Their Cycling Behavior in Organic Electrolyte Solutions

Masayuki Morita, Takuma Izumi, Yuya Noguchi, Masahiro Tokita, Kenta Fujii, and Nobuko Yoshimoto

morita@yamaguchi-u.ac.jp

Carbon materials having high specific surface area, such as activated carbon (AC), have been used as the electrodes of electric double-layer capacitors (EDLCs). In EDLCs using organic nonaqueous electrolytes, water contents in the solution phases significantly influence the capacitor performances [1]. Those carbon materials usually contain small amounts of water in their pore structures. However, their influences on the capacitor performances are still unclear because it is rather difficult to determine quantitatively the water content in AC after proper thermal treatments. We have proposed a simple method that can estimate the water contents in high surface area carbon materials [2]. In this paper, the effects of the residual water in the electrode on the capacitor performances are investigated.

Commercially available AC was used as the electrode material. For the estimation of water in AC, acetonitrile (AN) and propylene carbonate (PC) of battery grade (water content < 5 ppm) were used as the organic solvents. Carbon materials properly treated were immersed in the solvents or in the solutions dissolving supporting electrolyte. Changes in the water content in the solution phase after the carbon immersion were monitored by a Karl-Fisher titration method. Capacitor performances of the carbon electrodes containing different amounts water were examined by constant-current cycling of a symmetric two-electrode cell.

The water content in AC was found to be kept almost equilibrium after vacuum-drying at 100 °C or above. The amounts of water released (desorbed) from AC after the vacuum-drying was generally higher in AN solvent than in PC solvent. This result would be caused by differences in the affinity of the solvent molecule with the pore-wall surface of AC. The Langmuir adsorption isotherms were obtained for AC in AN and PC solvents, after the assumption that the water adsorbed inside AC keeps adsorption equilibrium with the water dissolved in the organic solvent [2]. The amount of water released from the pore structure of AC depended on the electrolytic salt in the solution phase.

AC samples with different water contents were obtained by changing the vacuum-drying conditions. Figure 1 shows the influences of the residual water in AC electrode on the variations in the capacitance and internal resistance during the constant-current cycling with high-voltage (3.5 V) loading. The residual water affects much on the variations in the capacitance and internal resistance of the cell with repeated cycles.

Supercapacitor cell voltages are too low and time constant too high for a typical capacitor's application – smoothing ac ripple in dc voltage converters. Modern electronic devices, such as computers, USB chargers, or mobile phones, have a typical rail voltage of 3.3 or 5 V and use capacitors within range of 4–10 V. Unfortunately, suitable electrolytic capacitors have very low energy density.

We have demonstrated [1] that in 1-butyl-1-methylpyrrolidinium dicyanamide (BMPDCA) ionic liquid a graphene electrode passivates at 10 V and at the same time the conductivity of the single-layer graphene sheet increases more than 5 times. The protective self-healing nanolayer formed is a new carbon-nitrogen material polydicyanamide (PDCA, identified by *in situ* infrared spectroscopy [2]) with dielectric constant value up to 9.8. In Figs. 1b and 2a it is shown that a large surface area reduced graphene oxide (RGO) electrode can be completely passivated – i.e. coated with a thin protective dielectric layer and have low leaking current density even at 10 V.

**Fig 1.** Electron microscopy images of an unmodified (a) and a passivated (b) RGO electrode (scale bar is 1  $\mu\text{m}$ ).

It is proposed that a hybrid capacitor can be constructed using a thinner RGO negative electrode and a passivated RGO positive electrode. Good stability (>10000 cycles), high efficiency (>99.8% coulombic) and time constants within 0.01 and 0.2 ms have been demonstrated for the passivated RGO electrodes. In the cell voltage range from 4 to 10 V, capacitors with RGO electrodes outperform any commercial capacitor technology by better energy density (Fig. 2b). Thus, the new technology proposes that graphene-based materials can dominate in the future capacitor market, currently worth US\$ 18 billion.

**Fig. 2.** a) Constant current charge-discharge curves [1] for the passivated and unmodified (blue line) RGO electrodes in BMPDCA. b) Energy density of PDCA and commercial capacitor technologies.

Activated carbon considered a mature material for many applications has introduced as electrochemical double layer capacitor (EDLC) active material for decades. For supercapacitor, tremendous efforts are devoted to understanding the correlation between specific surface area (SSA) of activated carbon and specific capacitance. Rare works are done with the pore size distribution (PSD) effect on electrochemical performance, not to mention inaccurate way to gain SSA or partial PSD through classical, macroscopic thermodynamic method which is not the most proper model for activated carbon [1] or material with micropores. With not only incorrect model but also much more complicated and broad PSD, how PSD affects the capacitance and equivalent series resistance (ESR) is still vague, even though ca. 0.7 nm was regarded as the most efficient pore size of carbide-derived carbon (CDC) which has quite narrow PSD for creating capacitance with TEABF<sub>4</sub>/ACN electrolyte [2].

DFT are powerful technique that describes sorption and behavior of inhomogeneous fluids confined in nanoporous materials [1] and QSDFT is recently developed approach and quantitatively accounts for surface heterogeneity effects to provide a more reliable pore size assessment and specific surface area [3]. In this work, the activated carbons developed by China Steel Chemical Corporation from coal tar pitch are analyzed by QSDFT and coin cell format EDLC are assembled with acetonitrile (ACN) and propylene carbonate (PC), respectively. The correlation of PSD and capacitor performance is found out through 4 different SSA activated carbons both in ACN and PC system and empirical equations are developed to unveil the most efficient pore offers highest specific capacitance per SSA and the most efficient pore improves ESR more significantly. With above information, electrochemical properties of activated carbon can be predicted by simple gas adsorption/desorption approach and it will be easier to tailor activated carbon by needs or demands.

Electrochemical double layer capacitors are currently being investigated by academic, governmental and industrial laboratories. The interest for these energy storage systems stems from their potential applications in portable electronic devices, energy recovery and transportation.

Carbon is currently the electrode material of choice for most practical devices due to its good capacitive behavior and performance and excellent chemical stability upon cycling. However, advances are needed to improve the energy density of carbon-based electrochemical capacitors. Approaches currently under investigation involve the use of quinone molecules, either dissolved in the electrolyte (so called redox active electrolyte), adsorbed or covalently grafted to a porous carbon material. In this presentation, we will present results for these systems by focusing on the charge/discharge behavior of full cells and their self-discharge. The advantages and limitations of these systems will be discussed.

# Effect of ZnO on Capacitive Properties of Core / Hybrid Shell Arrays

Complex core-shell nano-architectures were synthesized and investigated for electrochemical energy storage application by employing ZnO nanorods as core array and polypyrrole (PPy) –graphene oxide (GO) hybrids as shells. The structure, morphology and electrochemical properties of core-shell arrays were investigated by XRD, FTIR and RAMAN spectroscopy. Cyclic voltammetry was performed in order to analyze the electrochemical properties and evolution of inner and outer shell charge. The results indicated a synergetic effect of ZnO nanorods and PPy-GO hybrids towards improved capacitance while a strong dependence of the capacitive performance of ZnO/PPy-GO core-shell arrays on deposition potential and deposition charge for ZnO arrays was revealed. These instructions are an example of what a properly prepared meeting abstract should look like. Proper column and margin measurements are indicated.

*qiu.jiang@kaust.edu.sa*

We propose a generic strategy for microsupercapacitor fabrication that integrates layers of reduced graphene oxide (rGO) and pseudocapacitive materials to create electrode heterostructures with significantly improving cycling stability and performance. Our approach involves a combination of photolithography and a simple transfer method of free-standing reduced graphene oxide film onto an Au/patterned photoresist bilayer. The resulting stack (rGO/Au/patterned resist/substrate) is then used for the electrochemical deposition of various pseudocapacitive materials before the final step of lift-off. To prove the viability of this method, we have successfully fabricated microsupercapacitors (MSCs) with the following interdigitated electrode heterostructures: MnO<sub>2</sub>/rGO, Co(OH)<sub>2</sub>/rGO and PANI/rGO. These MSCs show better performance and cycling stability compared to the single layer, (i.e., rGO-free) counterparts. The interdigitated electrode heterostructures result in MSCs with energy densities in the range of 3-12 mWh/cm<sup>3</sup> and power densities in the range of 400-1200 mW/cm<sup>3</sup>, which is superior to the Li thin film batteries (E = 10 mWh/cm<sup>3</sup>), carbon, and metal oxide based MSCs (E = 1-6 mWh/cm<sup>3</sup>). These results can be explained by a facilitated nucleation model, where surface topology of the rGO film creates a favourable environment for the nucleation and growth of pseudocapacitive materials with strong interfacial contacts and enhanced surface area. This approach opens up a new avenue in fabricating MSCs involving a variety of heterostructures combining electrical double layer carbon type with Faradaic pseudocapacitive materials for enhanced electrochemical performance.

# **Polyaniline-RuO<sub>2</sub> Core-Shell Nanostructured Arrays for Very Stable and High Performance Pseudocapacitors**

Chuan Xia, Wei Chen, Xianbin Wang, Mohamed N. Hedhili, Nini Wei, Husam N. Alshareef\*

*Mr. C. Xia, Dr. W. Chen, Dr. X. B. Wang, Dr. M. H. Hedhili, Ms. N. N. Wei, Prof. H. N. Alshareef

Thuwal, 23955-6900, Kingdom of Saudi Arabia  
chuan.xia@kaust.edu.sa*

Conducting polymers such as polyaniline (PAni) show great potential as pseudocapacitor materials for electrochemical energy storage applications. Yet, the cycling instability of PAni resulting from structural alteration is a major hurdle to its commercial application. Here we report the development of nanostructured PAni-RuO<sub>2</sub> core-shell arrays as electrodes for highly stable pseudocapacitors with excellent energy storage performance. A thin layer of RuO<sub>2</sub> grown by atomic layer deposition (ALD) on PAni nanofibers plays a crucial role in stabilizing the PAni pseudocapacitors and improving their energy density. The pseudocapacitors, which are based on optimized PAni-RuO<sub>2</sub> core-shell nanostructured electrodes, exhibit very high specific capacitance (710 F g<sup>-1</sup> at 5 mV s<sup>-1</sup>) and power density (42.2 kW kg<sup>-1</sup>) at an energy density of 10 Wh kg<sup>-1</sup>. Furthermore, they exhibit remarkable capacitance retention of ~88% after 10,000 cycles at very high current density of 20 A g<sup>-1</sup>, superior to that of pristine PAni based pseudocapacitors. This prominently enhanced electrochemical stability successfully demonstrates the buffering effect of ALD coating on PAni, which provides a new approach for the preparation of metal-oxide/conducting polymer hybrid electrodes with excellent electrochemical performance.

# Facile Fabrication of High-Performance All-Solid-State Micro-supercapacitors through Laser Micromachining

Hsin-Chieh Huang, Hsisheng Teng

*Department of Chemical Engineering and Research Center for Energy Technology and Strategy, National Cheng Kung University, Tainan 70101, Taiwan  
hteng@mail.ncku.edu.tw*

Micro-supercapacitors (MSCs) are designed and fabricated to serve as power sources or energy storage units in microelectronic devices [1]. We employed a novel approach to fabricate MSCs based on activated mesophase pitch (aMP) carbon as the active material in conjunction with laser micromachining on a substrate deposited with aMP. The aMP carbon, which contains hierarchically connected micropores and mesopores, was effective for storing charge at high rates and high voltages [2]. The in-plane interdigitated architecture of the microelectrodes obtained from laser patterning was clearly defined and the design effectively facilitated transport of electrolyte ions into carbon micropores. Electrochemical measurements indicated that the specific capacitance of the all-solid-state aMP-based MSC was  $10 \text{ F cm}^{-3}$  at  $1 \text{ V s}^{-1}$ . At a high scan rate of  $100 \text{ V s}^{-1}$ , a specific capacitance of  $2.7 \text{ F cm}^{-3}$  was recorded, which is an unprecedented performance for supercapacitors. The combination of the highly accessible area of aMP and the interdigitated in-plane design resulted in a high-frequency response of the MSCs, showing a resistive-capacitive time constant of 7 ms. These impressive performances of the MSCs indicate that the developed fabrication methods are compatible with current fabrication processes for microelectronic devices and could provide a favorable opportunity for developing various micro- and nano-sized energy devices to satisfy the requirements of portable, miniaturized electronic equipment.

# Improving energy performance of electrochemical capacitors by combining redox reaction with hydrogen storage phenomena

Jakub Menzel, Krzysztof Fic, Elzbieta Frackowiak

*Institute of Chemistry and Technical Electrochemistry, Poznan University of Technology,  
Berdychowo 4, 60-965 Poznan, Poland  
[elzbieta.frackowiak@put.poznan.pl](mailto:elzbieta.frackowiak@put.poznan.pl)*

The major disadvantage of modern C/C supercapacitors is a limited energy output of 10Wh/kg for the device and a high cost of 1Wh. In order to reach the demand of market, the goal for new supercapacitors is energy density at the level of 30 Wh/kg with a cost of 1Wh lower than 1\$. The energy value of these devices is strictly related to two parameters, i.e. capacitance value and operating voltage range ( $E=0.5C \cdot V^2$ ). The capacitance of supercapacitors depends on the active surface area of electrode material, electrolyte accessibility to this surface and distance between electrodes. On the other hand, the voltage limit of these devices is strictly related to electrochemical stability window of electrolyte used. Keeping in mind only these two parameters the most preferable systems are organic ones due to a significant capacitance value ( $\sim 100$  F/g for active electrode material) and high voltage limit ( $\sim 2.7$ V for acetonitrile based electrolytes). The disadvantage of these systems is high cost of Wh/kg and usage of harmful organic solvents. The alternative for these systems might be capacitors with cheap neutral aqueous electrolytes. The advantage of such solutions are low cost, environmental friendliness and possibility of capacitance improvement by utilization of redox active species as source of pseudocapacitance. But still even with capacitance reaching  $\sim 300$  F/g such systems are characterized by relatively low energy performance due to narrow electrochemical voltage window of water; theoretically, water based electrolytes are limited to maximum 1.23V, but due to high hydrogen evolution overpotential in several electrolyte solutions it is possible to extend the maximum voltage window to 1.5V. In such condition when negative electrode reaches very low potential value one can expect hydrogen electrosorption on carbon material and increased capacitance.

This work reports on the influence of different cations attracted on the negative electrode and iodine/iodide redox shuttle operating on the positive side. It has been found that the proper separation of electrolytes for positive and negative electrode allows extension of the voltage window above 1.2V and enhancement of capacitance of negative electrode by hydrogen electrosorption/desorption reaction. Such combination of electrolytes can severely increase the energy and power performance of aqueous based capacitors.

Ultracapacitors, also known as supercapacitors, have the potential to meet the increasing power requirements of energy-storage systems for automotive applications. As compared to batteries, ultracapacitors offer a higher power density, higher efficiency, and longer shelf and cycle life. Because the performance of an ultracapacitor depends on temperature, it is important to calculate accurately the thermal behavior of a single ultracapacitor cell and the module composed of multiple ultracapacitor cells for the efficient and reliable systems integration of an ultracapacitor in automotive applications.

In this work, modeling is performed to study the thermal behavior of an ultracapacitor module. The ultracapacitor module is subject to the charge/discharge cycling with constant-current between 1.35V and 2.7V. The validation of the modeling approach is provided through the comparison of the modeling results with the experimental measurements.

Fig. 1 shows the schematic diagram of the ultracapacitor module composed of the 18 ultracapacitor cells (3.7V/3000F) from LS Mtron Ltd. In Fig. 2, the variation of surface temperature with time from the experiment is compared with that from modeling during the charge-discharge cycles with the constant current of 200 A.

# Performance improvement of AC/AC capacitors in aqueous medium through selection of current collectors

Paula Ratajczak, Adam Ślesięński, Elżbieta Frąckowiak, François Béguin  
ICTE, Poznan University of Technology  
Berdychowo 4, 60-965, Poznan, Poland  
paula.ratajczak@doctorate.put.poznan.pl

Lately, aqueous electrolytes based on neutral alkali sulfates revealed the possibility of increasing the value of maximum cell potential, owing to a high over-potential for di-hydrogen evolution at the negative activated carbon (AC) electrode. We demonstrated that AC/AC capacitors with stainless steel current collectors in aqueous  $\text{Li}_2\text{SO}_4$  exhibit long time performance under floating up to 1.5 V [1]. Notwithstanding, for further development of these capacitors, there is still a need to explore low cost, safe and environment friendly components, while keeping optimal performance of the system.

In this study, we show that easily available and relatively cheap nickel is an alternative material to corrodible stainless steel. Another objective of the presentation is to combine the two kinds of current collectors, in their most advantageous operation conditions, in order to extend the lifetime of an AC/AC capacitor in  $\text{Li}_2\text{SO}_4$ . Cyclic voltammetry, galvanostatic cycling, electrochemical impedance spectroscopy and floating up to high cell potential have been used to detect the onset of reactions involving the electrolyte and current collectors, and thereof the performance limits of the supercapacitors. The time constants of 0.46 s and 0.57 s for the cells with nickel (-)/nickel (+) and nickel (-)/steel (+) configurations, respectively, reveal a favourable impact of nickel on the dynamics of charge exchange in the cell, when compared to 0.80 s with steel (-)/steel (+) configuration. Moreover, the size of the high-frequency semi-circle in Figure 1a reveals that the supercapacitor with combined collectors presents the lowest charge transfer resistance value (0.94  $\Omega$ ), when compared to 1.1  $\Omega$  and 1.24  $\Omega$  for nickel (-)/nickel (+) and stainless steel (-)/stainless steel (+) cell, respectively. Finally, the most stable resistance values (with no corrosion of the positive current collector) during floating at 1.6 V were revealed by the cell with nickel (-)/stainless steel (+) combination of collectors, owing to -105 mV shift of the operating electrode potentials. As in the case of symmetric nickel (-)/nickel (+) cell, the performance of the asymmetric one is not much disturbed by the appearance of nickel oxidation compounds on the edges of the negative current collector, and the resistance remains stable till the end of the test (Figure 1b) [2]. The presentation will also consider the parameters which are responsible for changes of electrochemical performance when using current collectors of different thickness and diverse origin.

**Figure 1.** Performance of AC/AC capacitors with different couples of current collectors in 1 mol L<sup>-1</sup>  $\text{Li}_2\text{SO}_4$ : (a) Nyquist impedance plot; (b) resistance evolution during floating at 1.6 V.

# Optimizing the high cell potential performance of AC/AC supercapacitors based on two aqueous electrolytes

Paula Ratajczak, Piotr Gajewski, François Béguin

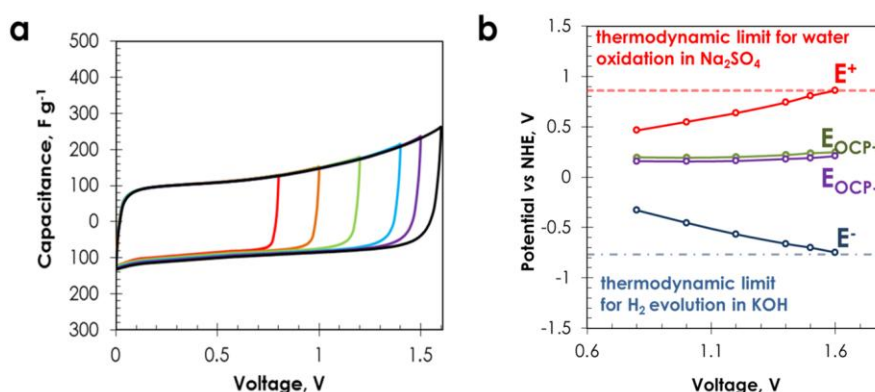

ICTE, Poznan University of Technology

Berdychowo 4, 60-965, Poznan, Poland

paula.ratajczak@doctorate.put.poznan.pl

In recent years, neutral aqueous electrolytes have been more and more often implemented in AC/AC electrochemical capacitors. They offer several important advantages as compared to solutions in organic solvents, such as high ionic conductivity allowing high power operation, environmental friendliness and possibility of manipulation in ambient conditions. Furthermore, as we already demonstrated, neutral 1 mol L<sup>-1</sup> Li<sub>2</sub>SO<sub>4</sub> displays good performance with stainless steel collectors under floating up to 1.5 V [1], which is more than the thermodynamic stability window of only 1.23 V in water medium. Therefore, it is interesting to search for solutions which would allow the operating cell potential to be further increased while using aqueous electrolytes.

In this context, we present a concept of AC/AC supercapacitor using two aqueous solutions of potassium hydroxide (0.5 mol L<sup>-1</sup> KOH) and sodium sulfate (1.0 mol L<sup>-1</sup> Na<sub>2</sub>SO<sub>4</sub>) as catholyte and anolyte, respectively, a cation exchange membrane as separator, and stainless steel collectors [2]. According to thermodynamic considerations, due to the pH difference between the two electrolytes (pH<sub>KOH</sub> = 13.2; pH<sub>Na2SO4</sub> = 6.6), the system is theoretically able to operate up to 1.62 V. We experimentally proved it by CVs in Figure 1a, where the curves are not featured by a current leap due to electrolyte reduction at the negative electrode and/or electrochemical oxidation of the positive carbon electrodes at the highest cell potential (1.6 V). Nevertheless, as verified by two-electrode cell experiment with reference electrode at cell potential of 1.6 V, the potential of the positive electrode exceeds the thermodynamic limit of electrolyte oxidation, while there is still some margin at the negative electrode before reaching dihydrogen evolution. An adjustment of positive and negative electrodes mass ratio (m<sub>+</sub>/m<sub>-</sub>=2.25) enables to extend the operating cell potential to 1.6 V, with E<sub>-</sub> = -0.748 V and E<sub>+</sub> = 0.852 vs NHE (Figure 1b).

**Figure 1.** (a) CVs (0.4 mV s<sup>-1</sup>) of AC/AC supercapacitor in (-) 0.5 mol L<sup>-1</sup> KOH / 1.0 mol L<sup>-1</sup> Na<sub>2</sub>SO<sub>4</sub> (+) recorded up to 0.8, 1.0, 1.2, 1.4, 1.5 and 1.6 V; (b) electrodes potential range vs. cell potential measured during galvanostatic cycling at 40 mA g<sup>-1</sup> on a cell with unequal electrode masses (m<sub>+</sub>/m<sub>-</sub>=2.25). E<sub>OCP</sub> - open circuit potential.

Strategies to enhance the operating cell potential by optimizing the AC electrodes, the current collectors and the design of the cation exchange membrane will be presented. Electrochemical techniques will be used to detect the onset of reactions involving the electrolyte and to critically discuss the possible performance optimization of this new electrochemical capacitor generation.

# Activated carbon electrode expansion during EDL charging in various salt aqueous electrolytes

Paweł Jeżowski, François Béguin

Poznan University of Technology, Institute of Chemistry and Technical Electrochemistry, Berdychowo 4, 60-965 Poznan, Poland

[pawel.jezowski@put.poznan.pl](mailto:pawel.jezowski@put.poznan.pl)

In recent years, the performance of electrical double-layer capacitors (EDLCs) has been investigated in a wide range of electrolytes. Especially, it has been demonstrated that high values of working cell potential up to 1.5 - 2.0 V can be reached with AC/AC (AC = activated carbon) capacitors in aqueous alkali sulphates [1-3]. Due to the low cost and environment friendly character of these media, and the high values of energy density which could be reached after further improvements, it is of interest to understand the mechanisms of ions storage using in-situ techniques.

In-situ dilatometry has been developed lately to investigate EDL capacitors. This technique was introduced in 1982 by Biberacher et al [4] to study the expansion of electrodes during electrointercalation in layered materials using organic electrolytes. In 2006, Hahn et al were the first to apply dilatometry during charging/discharging of EDLCs in organic electrolyte, and they showed a relatively unexpected expansion of electrodes [5].

In this work, in-situ dilatometry is applied to study the expansion of activated carbon electrodes in aqueous alkali ( $\text{Li}^+$ ,  $\text{Na}^+$  and  $\text{Cs}^+$ ) sulfates. At -0.4 V vs AC reference electrode, the value of expansion reaches around 0.200  $\mu\text{m}$  for  $\text{Cs}^+$ , while for  $\text{Li}^+$  and  $\text{Na}^+$  the expansion is close to 0.150  $\mu\text{m}$ . The dramatic increase of expansion at -1.030 V vs AC reference, e.g., 1.150  $\mu\text{m}$  and 1.650  $\mu\text{m}$  for  $\text{Li}^+$  and  $\text{Cs}^+$ , respectively, might be attributed to hydrogen chemisorption in the working AC electrode, which should theoretically start to take place at ca -0.59 V vs AC reference at pH=6.5. The higher expansion in 1 mol  $\text{L}^{-1}$   $\text{Cs}_2\text{SO}_4$  as compared to 1 mol  $\text{L}^{-1}$   $\text{Li}_2\text{SO}_4$  suggests that alkali ions are stored desolvated in the porosity of AC. This interpretation will be discussed in light of complementary experiments in order to better elucidate the state of adsorbed ions.

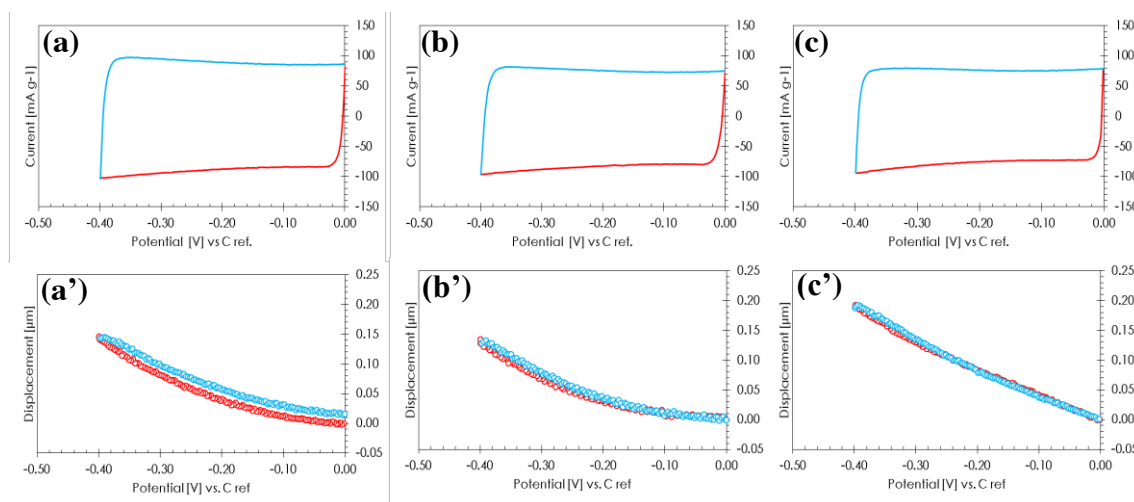

Fig. 1 Cyclic voltammograms (1  $\text{mV s}^{-1}$ ) and expansion of AC electrodes (charging – red; discharging – blue) during negative polarization scanning: (a – a') in 1 mol  $\text{L}^{-1}$   $\text{Li}_2\text{SO}_4$ , (b – b') in 1 mol  $\text{L}^{-1}$   $\text{Na}_2\text{SO}_4$ , (c – c') in 1 mol  $\text{L}^{-1}$   $\text{Cs}_2\text{SO}_4$ .

Supercapacitors have high power density, long cycle life, fast charge/discharge rates, and low manufacturing costs, which have been extensively used in civilian and military areas.<sup>1</sup> Carbon materials as promising electrode materials for supercapacitors show excellent electrochemical performance due to their high surface area and good electrical conductivity.<sup>2,3</sup> However, carbon-based electrode materials in supercapacitor applications offer lower specific capacitance and energy density, when compared with pseudocapacitor electrode materials such as metal oxides and conductive polymers.

In this work, phytic acid was selected as protonic acid dopant to synthesize 3D network polyaniline (PANI) nanofibers (**Figure 1**). Then, PANI nanofibers were transformed to nitrogen and phosphorus co-doped carbon nanofiber (NPCNFs) by pyrolysis and porous nitrogen and phosphorus co-doped carbon nanofibers (PNPCNFs) by chemical activation. NPCNFs have a high specific surface area, large pore volume and heteroatom doping, which could enhance the electrochemical performance for supercapacitors. Therefore, NPCNFs have a high specific capacitance of 280 F g<sup>-1</sup> measured in three-electrode system (1 A g<sup>-1</sup>) and a high energy density of 16.3 Wh kg<sup>-1</sup> measured in two-electrode system.

**Figure 1.** (a) Digital photographs of (left) phytic acid, (middle) aniline/phytic acid, and (right) polyaniline (PANI) nanofibers in a glass bottle. (b) TG curve of NPCNFs from the pyrolysis of PANI nanofibers under an inert atmosphere. (c, d) Cyclic voltammetry curves at 10 mV s<sup>-1</sup> and Ragone plot of symmetric capacitor based on PNPCNFs.

# **Influence of 1,2-Dimethoxyethane Additive on the Electrochemical Characteristics of EMImTFSI Based Electrolytes for Supercapacitors**

Jaanus Eskusson, Alar Jänes, Enn Lust  
*Institute of Chemistry, University of Tartu, Estonia*  
*14a Ravila Str.*  
*Jaanus.Eskusson@ut.ee*

The electrochemical characteristics of the electrical double layer capacitors (so-called supercapacitors) consisting of the microporous titanium carbide derived carbon (TiC-CDC) electrodes and 1M  $(\text{C}_2\text{H}_5)_3\text{CH}_3\text{NBF}_4$  solutions in pure 1-Ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide (EMImTFSI) and mixtures with 1,2-Dimethoxyethane (by different volume ratios) based electrolytes have been studied using cyclic voltammetry and electrochemical impedance spectroscopy methods.

These systems have been selected because mentioned solvents have different relative macroscopic dielectrical permittivity ( $\epsilon$ ), different viscosities and melting temperatures as well as different dipole moment values (vertical component). The specific capacitance, phase angle and series resistance values dependent on the solvent system used have been established. It was shown that the electrolyte solution chemical composition has noticeable effect on the electrochemical characteristics calculated.

Specific conductivity and viscosity values have been obtained and compared with electrochemistry data. The region of ideal polarisability  $\Delta E \geq 3.5$  V has been achieved in all mixed electrolytes investigated. The limiting capacitance, characteristic time constant and complex power values depend noticeably on the electrolyte studied, i.e. on the viscosity and specific conductivity of electrolyte solution used.

**Abstract:** Pores and surface functional groups are created on graphene nanosheets (GNSs) to improve supercapacitor properties in a butylmethylpyrrolidinium-dicyanamide (BMP-DCA) ionic liquid (IL) electrolyte. The GNS electrode exhibits an optimal capacitance of 330 F g<sup>-1</sup> and a satisfactory rate capability within a wide potential range of 3.3 V at 25 °C. Pseudocapacitive effects are confirmed using X-ray photoelectron spectroscopy. Under the same conditions, carbon nanotube and activated carbon electrodes show capacitances of 80 and 81 F g<sup>-1</sup>, respectively. Increasing the operation temperature increases the conductivity and decreases the viscosity of the IL electrolyte, further improving cell performance. At 60 °C, a symmetric-electrode GNS supercapacitor with the IL electrolyte is able to deliver maximum energy and power densities of 140 Wh kg<sup>-1</sup> and 52.5 kW kg<sup>-1</sup> (based on the active material on both electrodes), respectively, which are much higher than the 20 Wh kg<sup>-1</sup> and 17.8 kW kg<sup>-1</sup> obtained for a control cell with a conventional organic electrolyte.

Over the past few decades, great interest has been devoted on porous carbon materials in energy storage and conversion devices, and gas sorbent applications owing to their cost-effectiveness, tunable microstructure, at ease of availability and surface functionalization [1]. Particularly in supercapacitor (SCs) energy storage system, as it stores energy by electrostatic interaction between electrode-electrolyte interfaces based on the Electrical double layer phenomenon, so the amount of charge stored directly dependent on the surface area of any electrode material [2]. Thus, Porous carbon material being considered as the potential electrode material for SC owing to large surface area, chemical stability and low cost [3]. A large variety of porous carbons of different dimensions have been studied as SC electrode materials. However, many of them showed disadvantages such as the high ionic resistance, low electrical conductivity and low compatibility of conductive pathways to store charge, which unfavorable for high energy storage and high power devices criteria. So the performance of SCs not only depends on the physical, but also intimately on the chemical properties of the electrode material. Alternately, the polarization of surface functional groups on carbon materials would indeed enhance the wettability in aqueous medium and decrease the necessity of high surface area or high porosity of electrode materials. However, instabilities of these surface functionalities matters the prolong life time of SCs [4]. Recently, several research groups have focused on adding electrochemically active species or mediators such as phenylenediamine, quinones, halides, transition metal sulfate in aqueous medium, so called redox active electrolytes (RAE), to enhance the energy storage in SCs. However, the irreversibility of RAE for long time and high self-discharge rate in the aqueous electrolyte are of major concerns for commercial realization. The above mentioned issues are addressed in our present study. We developed novel nano-channel carbon structures and utilized in optimized RAE, hydroquinone, mediated electrolyte system. The electrochemical performance in two electrode system showed excellent supercapacitor performance in terms of energy storage ( $22 \text{ Wh kg}^{-1}$ ), pro-long cycle life (15000 cycles), and self-discharge (10 hours).

## Abstract

Supercapacitors are the energy storage devices having superior power density than battery and recently developed materials have improved the energy density to compete with battery. In addition to that supercapacitors have high cycle life and very high dynamic charge propagation [1]. Metal oxides are the recent materials of interest due to their high capacitance and fast redox response. Among the metal oxides, manganese oxides ( $\text{MnO}_2$ ) are highly favored due to its high energy density, natural friendliness and high natural abundances.

In the present investigation nano composite materials of reduced graphene oxide and  $\text{MnO}_2$  nano rods were synthesized using hydrothermal method. Graphene oxide was prepared using modified Hummers's method [2]. The as prepared graphene oxide was mixed with potassium permanganate and placed inside the Teflon lined autoclave. The mixture was treated at  $170^\circ\text{C}$  for 24 hrs, and the nano composite material was formed. X-ray diffraction analysis has revealed the formation of  $\text{MnO}_2$ . Atomic Force microscopy (AFM) measurements as shown in Fig. 1 A have detected the formation of graphene sheets, the thickness of the grapheme sheets were obtained around 1.1 nm. Scanning electron microscopy (SEM) of the nano composite material has shown that the graphene sheets were well embedded with  $\text{MnO}_2$  nano rods, as shown in Fig.1 B.

Electrochemical measurements were carried out by recording the cyclic voltammetry, electrochemical impedance and the charge discharge measurements in 0.5 M  $\text{Na}_2\text{SO}_4$  solution. The materials remained stable in continuous cyclic voltammetry measurements. Strong contribution of the Warburg parameter in Nyquist plot of the electrochemical impedance measurement has revealed diffusion of charged species inside the porous structure of the composite material. The charge discharge property of the materials is shown in Fig. 1 C. Stable charge discharge characteristics were obtained for the experiments carried out up to 400 cycles. The redox property was reversible with no signature of material degradation due to the redox reaction was observed. The discharge specific capacitance of  $650\text{ Fg}^{-1}$  was observed at the discharge current density of  $2\text{ Ag}^{-1}$ . Manganese oxide nano composite material exhibits the supercapacitor property by insertion/deinsertion of proton and alkali metal ions in acidic and alkaline solution respectively during the charge-discharge cycle [2]. Current mapping of the substrate using scanning electrochemical microscopy (SECM) has detected the high capacitance of the substrate. SECM approach curves have shifted from negative feedback to positive feedback response at different levels of charging of the capacitor.

Figure 1 (A) AFM topograph of the  $\text{MnO}_2$  deposits (B) SEM micrograph (C) Charge discharge cycle of the  $\text{MnO}_2$ /graphene oxide nano composite material.

A comprehensive report about the characterization of the deposits, their supercapacitor behavior, electrochemical mapping and the transport of charge through the deposits will be presented in the conference

Graphene can be prepared from a graphite intercalation compound (GIC)<sup>1</sup> with acceptor-type intercalator, FeCl<sub>3</sub>.<sup>2</sup> When the FeCl<sub>3</sub>-GIC is treated with primary amines at 90 °C for 6 h, the GIC expands to a few layers.<sup>3</sup> The expansion is further facilitated, as the alkyl chain of primary amines becomes longer, while tertiary amines cannot penetrate inside the GIC because of their structural steric hindrance. The primary amine adsorbed in the GIC is oriented to form a bilayer by an indirect reactions among FeCl<sub>3</sub>-graphene-amine, and this process plays an important role in the expansion of the GIC, in contrast to the reaction of primary amines with donor-type GICs.<sup>4</sup> Then the expanded-GIC is sonicated to exfoliate the graphene sheets. The obtained material exhibited a superparamagnetic property due to the remaining iron compounds. This approach using FeCl<sub>3</sub>-GIC and primary amine is preferable for the mass production of graphene because of the mild reaction conditions and the short treatment time for exfoliation from the chemically stable FeCl<sub>3</sub>-GIC. Moreover, the magnetization of graphene nano-composites could be useful for magnetic-recovery processes, electromagnetic heating, and the other electrochemical applications.

Lithium ion secondary batteries and supercapacitors are currently being used electric vehicles and energy storage devices [1]. Lithium ion secondary batteries and supercapacitors have high energy density and power density, respectively. Hybrid supercapacitors are energy storage devices which combine respective advantages of lithium ion secondary batteries and supercapacitors. The H<sub>2</sub>Ti<sub>12</sub>O<sub>25</sub> is expected to have better electrochemical performance than Li<sub>4</sub>Ti<sub>5</sub>O<sub>12</sub> as an anode material in hybrid supercapacitors. In this paper, we designed using activated carbon (AC) as a cathode and H<sub>2</sub>Ti<sub>12</sub>O<sub>25</sub> with carbon-AlPO<sub>4</sub> binary coating as an anode. We also investigated the effects of the carbon-AlPO<sub>4</sub> binary coating on the electrical conductivity and the electrochemical performance. [2,3].

Recently, the new energy storage device called hybrid supercapacitor has been studied to implement higher power density (than lithium secondary batteries) and energy density (supercapacitor) for EVs. The hybrid supercapacitor combining the advantage of both supercapacitors and lithium secondary batteries has been studied by many researchers. We proposed the combination of activated carbon as cathode,  $\text{H}_2\text{Ti}_{12}\text{O}_{25}$  (HTO) as anode by previous study [1, 2]. The HTO has flat potential plateau at approximately 1.55V and capacity of 236mAh/g [3]. In this study, to improve power and energy density [4], we fabricated hybrid supercapacitor using hybrid anode of Activated carbon- $\text{H}_2\text{Ti}_{12}\text{O}_{25}$  materials and activated carbon as a cathode.

# Pulse Electropolymerization Synthesis of Polypyrrole Layers on Multiwalled Carbon Nanotubes coated Cotton Fabrics

Caihong Liu, Yaping Zhao, Hangyue Zhu, Hong Zhao, Zaisheng Cai  
*College of Chemistry, Chemical Engineering & Biotechnology, Donghua University, Shanghai, China*  
E-mail address: [zhaoyaping@dhu.edu.cn](mailto:zhaoyaping@dhu.edu.cn)

With the development of portable wearable electronics, flexible energy materials are being paid more and more attention. Cotton fabric, one of the most common materials in the textile industry, with a hierarchical structure and hydrophilic functional groups such as hydroxyl groups, has been employed as a substrate in flexible electrodes in order to reduce the weight of the substrate and boost the specific surface of the active material<sup>[1-3]</sup>. In this work, a new in-situ preparation method of flexible electrode materials is exploited, using a pulse electropolymerization technique is used to fabricate micrometre particles of polypyrrole (PPy) on conductive cotton fabrics, which is pre-coated with multiwalled carbon nanotubes (MWNT) by a 'dip and dry' method, from an aqueous solution containing cetyltrimethyl ammonium bromide (CTAB) and potassium chloride (KCl) without using any chemical additives. The conductivity of PPy@MWNT/Cotton is controlled by changing the applied voltage, pulse duration and pulse cycle. The obtained fabrics are characterized by fourier transform infrared spectroscopy (FTIR), X-ray powder diffraction (XRD) and scanning electron microscopy (SEM), and the electrochemical properties are examined by cyclic voltammetry, charge/discharge analysis. The cyclic voltammetry test further reveals that the fabric electrodes showed a specific capacitance of  $180 \text{ F} \cdot \text{g}^{-1}$  and good cycling performance (exceeding 90 % capacitance retention after 1000 cycles) in aqueous electrolyte. The developed method is simple and can be directly applied in natural fiber, which has good prospects for developing flexible electrode materials.

Hybrid-capacitor systems have been enthusiastically developed in order to augment the energy density of conventional electric double layer capacitor systems [1-2]. One of the representative cases is the combination of a negative electrode with faradic Li-intercalation (e.g., Li<sub>4</sub>Ti<sub>5</sub>O<sub>12</sub> (LTO)) and a positive electrode with non-faradic anion adsorption (e.g., activated carbon (AC)), used in lithium-based electrolytes (e.g., lithium tetrafluoroborate (LiBF<sub>4</sub>) dissolved in propylene carbonate (PC)). So far, the operating voltage of LTO/AC hybrid capacitors using PC-based electrolyte systems has been limited to 3.0 V, although the energy density of the hybrid capacitor can be easily increased with an increment of its operating voltage [3]. Previously, the degradation mechanism for LTO/AC system over 3.0 V was investigated; especially focusing on the electrochemical behaviour at the LTO / electrolyte interface [4]. Summarized results suggest that the degradation over 3.0 V is mainly due to the H<sub>2</sub>-based gas evolution resulted from the reduced decomposition of PC on LTO surface.

In this report, based on the elucidated degradation mechanism, linear sulfones were tested as high-withstand-voltage solvents and the potential replacement of PC. The LTO / AC cells were assembled as various forms (coin cell, H-type cell, laminate cell and also three electrode cells using a lithium metal reference) depending on a purpose, in 1 M LiBF<sub>4</sub> / PC or 1 M LiBF<sub>4</sub> / ethyl isopropyl sulfone (EiPS [5], Fig.1). Float durability tests were performed on the cells at 3.5 V. After aging tests, we analyzed the gaseous products of the cells by gas chromatography. Among tested samples, the system using EiPS showed the most promising performances. The EiPS system showed the stable electrochemical performance even at the high cell voltage of 3.5 V with significant suppression of the evolved gas volume (Fig.1). The EiPS system is indicated the excellent cycleability, maintaining 95 % of the initial capacity over 1000 cycles (Fig.2).

Fig.1 The amount of generated gas after float durability tests at 3.5V.

Fig.2 Results of Charge-Discharge cycle tests for LTO / AC cells using PC system and EiPS system

Phosphate cathode materials such as LiFePO<sub>4</sub> (LFP), LiMnPO<sub>4</sub> (LMP), and Li<sub>3</sub>V<sub>2</sub>(PO<sub>4</sub>)<sub>3</sub> (LVP) have been regarded as attractive active materials for hybrid electrical energy storage (EES) system, because of their high thermal stability and superior safety properties provided by the stable (PO<sub>4</sub>)<sup>3-</sup> unit. In particular, phospho-olivine LFP has attracted much attention for its excellent cyclability with its decent theoretical capacity of 170 mAh g<sup>-1</sup> at reaction potential of 3.4 V vs. Li/Li<sup>+</sup> [1]. However, its lithium storage performances are limited by its poor rate capability, meaning fast decay of specific capacity at high charge-discharge rate, owing to its intrinsic low electrical conductivity (10<sup>-9</sup> - 10<sup>-10</sup> Ω<sup>-1</sup> cm<sup>-1</sup>) and slow diffusion of Li<sup>+</sup> (10<sup>-14</sup> - 10<sup>-15</sup> cm<sup>2</sup> s<sup>-1</sup>) [2]. To overcome these limitations, we have proposed new concept of three - phase structure (Fig.2) containing crystalline LFP (= Core), amorphous LFP (= Shell 1), and hollow structured carbon; Ketjen Black (KB) (= Shell 2) synthesized using our original *in-situ* ultracentrifugation materials processing technology (UC process) [3]. The encapsulated crystalline and amorphous LFP nanoparticle within the KB prepared by UC-process improves the electronic conductivity and Li<sup>+</sup> diffusivity in the whole LFP/KB composites, simultaneously producing a amorphous phase of LFP in the exterior particles that acts as excellent rate performance owing to high Li-ion diffusion coefficient of LFP. Additionally, the three-layer structure induces peculiar electrochemical behavior such as the slope like charge discharge profile, indicating the existence of the solid solution dominates. This LFP/KB composite enabled a 100C rate (36 seconds) discharge with 160 mAh g<sup>-1</sup>, and 82% of capacity retention at the slowest discharge rate of 1C (Fig.2). Such an ultrafast charge-discharge performance opens the possibility of using LFP as a cathode material for ultrafast lithium ion batteries with a stable cycle performance over 2,000 cycles at a 10C rate, maintaining 90% of the initial capacity.

The commercial pursuit of hybrid (asymmetric) capacitor systems has been gradually increasing for the applications such as a system stabilizer of microgrid system, uninterruptible power supply (UPS), and energy storage of compact electric vehicles. A next-generation capacitor; Nano-hybrid capacitor (NHC), comprising nanocrystalline lithium titanate (LTO) grafted on carbon nanofiber for negative and activate carbon (AC) for positive electrodes, has achieved 3 times higher energy density than that of conventional EDLC, while maintaining the power density of EDLC [1]. Establishment of LTO-NHC mass production technology is scheduled to 2017-2018 [2]. Next step is to increase the energy density of the LTO-NHC system without sacrificing its high performance and reliability. One approach is to replace LTO anode by alternative materials with higher theoretical capacity (LTO = 175 mAh g<sup>-1</sup>). Bronze-typed TiO<sub>2</sub> (TiO<sub>2</sub>(B)) has attracted much attention for such an application because of its high theoretical capacity (335 mAh g<sup>-1</sup>) and the safe redox potential of 1.6 V vs. Li/Li<sup>+</sup>. Using the combination of our original ultracentrifugation (UC) treatment and hydrothermal treatment, nano-rectangular TiO<sub>2</sub>(B) (4-7 nm) has been successfully synthesized with the existence of nano carbons (e.g., single-walled carbon nanotubes (SWCNT), multi-walled CNTs (MWCNT), and Ketjen Black (KB)). The UC-treated TiO<sub>2</sub>(B) has the minimized *b*-axis length (4 nm) as small as previous reports [3], while our nanocrystalline(nc)-TiO<sub>2</sub>(B) is highly dispersed and directly attached on the surface of nanocarbons owing to our *in-situ* synthesis method. The UC-HT TiO<sub>2</sub>(B)/nanocarbon composite electrodes showed an excellent electrochemical performance; the high capacity of 236 mAh g<sup>-1</sup> per TiO<sub>2</sub>(B) at an ultra high rate of 300C (in case of MWCNT). Electrochemical performances of new-class hybrid capacitors based on the UC-treated TiO<sub>2</sub>(B) will be also presented. TiO<sub>2</sub>(B)-NHC, comprising a negative electrode of ultrafast nc-TiO<sub>2</sub>(B)/nanocarbon and a positive electrode of Super-Growth (single-walled) Carbon Nanotube (SGCNT) may enlarge the operation voltage of the NHC from 2.75 V (LTO-NHC) to 3.5-4.0 V (TiO<sub>2</sub>(B)-NHC), increasing the energy density of the device to 1.3-1.7 times of LTO-NHC.

This study demonstrates the criteria for the operated potential window in activated carbon based electrical double-layer capacitors (EDLCs) in organic electrolyte. In this work, we utilize the floating test for 3000s to define the operated potential window at the beginning. The results from floating test simply show the potential window from - 2.1 V to 0.3 V against Ag / AgNO<sub>3</sub> is the proper potential window. Moreover, a negative activated carbon electrode (- 2.1 V) and a positive activated carbon electrode (0.3 V) are assembled in a 2.4 V symmetric cell. A symmetric cell charge- discharge 1152 cycles and the times of cycles are equal to have floating test 9hr. After charge- discharging, the specific capacitance decay 27 % and the electrochemical impedance spectroscopic (EIS) analyses show the crucial reason in the cell. From EIS results, the resistance increase as cycle increasing. Consequently, the floating test with EIS is a suitable method to efficiently define the operated potential window. The operated potential window from - 1.9 V to 0.2 V against Ag / AgNO<sub>3</sub> is stable for charge- discharge test on critical potential ranging from 1.9 V to 2.1 V for 10000 cycles and only 8 % of specific capacitance decay. Besides, the EIS results before and after charge- discharge 10000 cycles still an ideal performance of EDLCs.

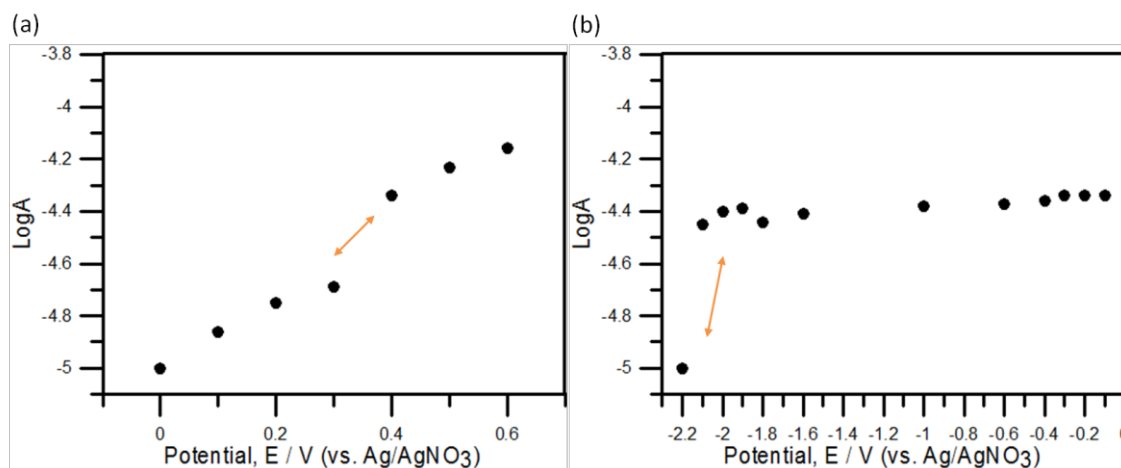

Figure 1 Log A from floating test 3000s against potential from (a) 0 V to 0.6 V and (b) - 0.1 V to - 2.2 V.

# Design and development of direct-growth in-situ doped Polypyrrole on carbon cloth as a high performance flexible supercapacitor

I. Shown<sup>1</sup>, A. Ganguly<sup>1</sup>, L. C. Chen<sup>2</sup>, K. H. Chen<sup>1,2</sup>

E-mail: [indrajit25@gmail.com](mailto:indrajit25@gmail.com)*

In the 21st century, the growing demand of the smart portable electronic gadgets, such as roll-up display, electric paper and wearable systems for smart electronics need to develop the flexible super capacitor with both high-power density and large energy density. Conducting polymers (CPs) are one of the most potential pseudo-capacitor materials for foundation of flexible-supercapacitors [1], motivating the existing energy storage devices towards the future advanced flexible electronic applications due to their high redox active specific capacitance and inherent elastic polymeric nature [2,3]. To the best of our knowledge, among conducting polymers, polypyrrole have shows better elasticity and conductivity than the polyaniline. To solve the flexibility of the stretchable supercapacitor, in this work, polypyrrole directly grown on the carbon cloth (CC) as electrodes for flexible supercapacitor. The electro deposition allowed well uniform deposition of polypyrrole coating on the carbon cloth current collector, thus offering a lower internal resistance for the novel direct growth binder free flexible electrode for supercapacitor application. The chemical composition and structural morphology of the electropolymerized polypyrrole with various inorganic dopants are characterized by Raman spectroscopy and scanning electron microscopy (SEM). The electrochemical performance of the fabricated electrodes was evaluated by cyclic voltammetry (CV), galvanostatic charge-discharge and electrochemical impedance spectroscopy (EIS). The high gravimetric capacitance of around 1100 F g<sup>-1</sup> per active mass of the polypyrrole has been achieved. These results clearly present a cost-effective and simple fabrication method of the polymers with enormous potential in flexible energy storage device applications. The detail electropolymerisation process and in-situ doping with various dopants and their electrochemical pseudo-capacitance performance with porosity and diffusion length study will be presented.

# An Energy Enhanced, Long-Life Supercabattery Based on High Discharge Efficiency Hybrid Electrodes

Yu-Wei Lin, Jun-Long Li, Chung-Hsiang Chao, Li-Duan Tsai, Jason Fang\*

Material and Chemical Research Laboratories, Industrial Technology Research Institute, Hsinchu, TAIWAN

No. 195, Sec. 4, Chung Hsing Rd., Chutung, Hsinchu 31040, TAIWAN

jasonfang0429@itri.org.tw

A supercabattery usually consists of asymmetric electrodes (i.e., internal series or parallel hybrid) with two different types of materials: one with supercapacitor feature and the other with battery characteristics. In this work, both types of materials were utilized in one electrode, forming the hybrid with voltage compensation to further improve the energy and the discharge efficiency of the energy storage device simultaneously. The electrochemical performances of the supercabattery were characterized by cyclic voltammetry, electrochemical impedance spectra, rate charge-discharge curves, and the cycle life tests. Such energy storage device shows the maximum energy density of  $20 \text{ Wh kg}^{-1}$  and the maximum power density of  $2500 \text{ W kg}^{-1}$ , respectively. Most importantly, the specific capacitance remains more than 80 % after 10,000 cycles, indicating good cycle life due to the enhanced stability of the hybrid electrodes.

# Hydrothermal prepared Al-doped $\alpha$ -MnO<sub>2</sub> nanotube and its electrochemical performances for supercapacitors

Yang Li, Jing Li, Huaqing Xie

School of Environmental and Materials Science Engineering, College of Engineering, Shanghai Second Polytechnic University, Shanghai 201209, P. R. China  
liyang@sspu.edu.cn

$\alpha$ -MnO<sub>2</sub> and Al-doped  $\alpha$ -MnO<sub>2</sub> were synthesized via hydrothermal method. The morphologies, structures and electrochemical performances of as-synthesized un-doped and doped  $\alpha$ -MnO<sub>2</sub> were studied. As-prepared  $\alpha$ -MnO<sub>2</sub> present nanotube shape under scanning electron microscopy (SEM) and high resolution transmission electron microscopy (HRTEM). The band gaps of  $\alpha$ -MnO<sub>2</sub> are investigated by ultraviolet-visible absorption spectroscopy, which indicates that the band gap of  $\alpha$ -MnO<sub>2</sub> decreases with Al doping. The electrochemical performances of un-doped and doped  $\alpha$ -MnO<sub>2</sub> as electrode materials for supercapacitor were conducted by cyclic voltammetry and galvanostatical charge/discharge tests. The specific capacitances of un-doped and Al-doped  $\alpha$ -MnO<sub>2</sub> respectively reach 204.8 F·g<sup>-1</sup> and 228.8 F·g<sup>-1</sup> under 50 mA·g<sup>-1</sup> current density. It was discovered that the electrochemical impedance of Al-doped  $\alpha$ -MnO<sub>2</sub> was decreased via Al doping in electrochemical impedance spectra, which was beneficial to increase its electrochemical specific capacitance. Enhanced specific capacitance and preferable cycling stability up to 1000 cycles of Al-doped  $\alpha$ -MnO<sub>2</sub> present favorable prospect to be applied in supercapacitors.

Fig.1 SEM image of as-synthesized  $\alpha$ -MnO<sub>2</sub>

Fig.2 HRTEM image of as-synthesized  $\alpha$ -MnO<sub>2</sub>

Fig.3 UV-visible spectra of as-prepared samples

In this work, we have successfully synthesize  $(\text{Ni-Co})(\text{OH})_2/\text{CNT}$  electrode for high energy density supercapacitors by a facile two-step fabrication method. The contact between the double hydroxides and CNT determines the determines the specific capacitance, high-rate performance, and stability of  $(\text{Ni-Co})(\text{OH})_2/\text{CNT}$  composites when they were used as capacitive materials with high/ultrahigh material loading. To improve the contact, galvanostatic method and pulse-rest method were used to deposit the double hydroxides on the CNT and their morphologies were characterized by SEM analysis. From the SEM it clearly states that the pulse-rest method can make the hydroxides deposit more easily into the pores of CNT, which would be good for increasing the surface area of active materials rather than by galvanostatic method. Moreover, the thickness of samples made by pulse-rest method was much thinner than that made by chronopotentiometry (3  $\mu\text{m}$  for pulse-rest; 9.5  $\mu\text{m}$  for CP). In charge/discharge tests, the electrode material containing four layers of hydroxides exhibited  $3.68 \text{ F cm}^{-2}$  at  $2 \text{ A g}^{-1}$ . On the other hand, by combining with activated carbon, the asymmetric supercapacitor exhibits a cell voltage of 1.70 V, energy density of  $19.8 \text{ W h kg}^{-1}$  and power density of  $25.5 \text{ kW kg}^{-1}$  at high current density of  $30 \text{ A g}^{-1}$  respectively. Furthermore, the areal capacitance was increased by fabricating more layers of composites.

Fig.1. The SEM images of side-view of the  $(\text{Ni-Co})(\text{OH})_2/\text{CNT}$  composites deposited at (a) constant current and (b) pulse current. (c) and (d) are the SEM images of CNT and graphite substrate.

# Asymmetric Capacitors to Improve the Charge Efficiency of the Capacitive Deionization

Jianyun Liu<sup>1</sup>, Miao Lu<sup>1</sup>, Jianmao Yang<sup>2</sup>, Wenshu Cai<sup>1</sup>, Jian Cheng<sup>1</sup>, Zhubiao Xiong<sup>1</sup>

<sup>1</sup>College of Environmental Science and Engineering, State Environmental Protection Engineering Center for Pollution Treatment and Control in Textile Industry, Donghua University, 2999 North Renmin Road, Shanghai 201620, China. <sup>2</sup>Research Center for Analysis & Measurement, Donghua University, Shanghai 201620, China

E-mail address: jianyun.liu@dhu.edu.cn

Desalination is currently a very topical area of research. Capacitive deionization (CDI), as a new desalination technology, is developing very fast in recent year for developing new electrode materials and optimization of setup and operation parameters[1], because of its merits such as low energy consumption, high water recovery rate, the renewability of the electrode and easy operation with no secondary pollution due to low applied voltage [2, 3]. Activated carbon (AC), as the most commonly used commercially available and cost efficient carbon material, is still attractive as the typical CDI electrode material because of its high specific surface area, low cost, easy manufacturing on a large scale [2, 4, 5]. Charge efficiency (CE), defined as the ratio of the equivalent charge of adsorbed salt to the total charge input during charging process, is one of the most important parameters in CDI cell. The charge efficiency can be increased by membrane-based CDI cell [6, 7] or by chemical modification of electrode surface [8, 9] to diminish co-ions migration/repulsion. During the development of new electrode materials, there are still many basic concepts, such as the difference between positive electrode and negative electrode, stability of the electrode material, effect of polarization, necessary to be understood.

In this presentation, several asymmetric activated carbon composite electrode capacitors such as negatively charged sulfonated graphene(GP-SO<sub>3</sub>H), positively charged aminated graphene (GP-NH<sub>2</sub>) were reported in order to well understand the effect of the properties of positive and negative electrode materials on charge efficiency. It demonstrates that the non-membrane chemical modification on the carbon electrode materials is feasible to arrive at the high charge efficiency. Meanwhile, effect of the amphoteric metal oxides on charge efficiency was also discussed. With zinc oxide/activated carbon composite electrode (ZnO/AC) as a candidate, we explored the different function of ZnO/AC positive and negative electrode on charge efficiency by assembling the asymmetric capacitor. The mechanism was analysed based on pH variation of electrode surface and the zeta potential of ZnO. This research provides a particularly important base and guidance for the selection of electrode materials in capacitive desalination in order to realize the long term stability.

These instructions are an example of what a properly prepared meeting abstract should look like. Proper column and margin measurements are indicated. Activated carbons have been widely used as electrode material because of their high surface area and low cost. However, EDLCs using activated carbons have been applied to the limited applications because they have lower energy density than that of battery. One of the best approaches to achieve both higher energy and higher power is to increase the acceptable working voltage of conventional EDLCs. The maximum voltage of EDLCs is limited to 2.5-2.7V due to the degradation caused by the adsorbed water and the acidic functional groups present in the pore with the electrolytes. In order to increase the working voltage, the heat treatment of the activated carbon at a temperature over 700 °C generally have been used to remove the absorbed water and the acid functional groups. However, heat treatment at higher temperature and a long time heat treatment cause a structural modification of the activated carbon, consequently resulting in a decrease in capacitance. In this study, in order to suppress the structure modification, Joule-heating method was applied to the commercial activated carbons.

# Reduced Graphene Oxide Decorated on MnO<sub>2</sub> Nanoflakes Grew on C/TiO<sub>2</sub> Nanowire Arrays for Supercapacitor

Sainan Yang, Yiju Li, Dianxue Cao, Guiling Wang\*

Key Laboratory of Superlight Materials and Surface Technology of Ministry of Education, College of Materials Science and Chemical Engineering, Harbin Engineering University, Harbin, 150001, P.R.China, E-mail: wangguiling@hrbeu.edu.cn

In recent years, supercapacitors draw a great deal of attention due to their high power density, long cycle life, rapid charging-discharging rates, wide range of operating temperatures and environmental friendliness<sup>[1]</sup>. As one type of transition metal oxides, MnO<sub>2</sub> is thought to be the most promising pseudo-capacitive material for its high-energy density, low cost, environmental compatibility, and natural abundance<sup>[2]</sup>. Unfortunately, the intrinsically poor electrical conductivity of MnO<sub>2</sub> is a hindrance to obtain high electrochemical performance. In order to overcome this issue, tremendous efforts have been focused on combining highly conductive materials such as graphene, carbon nanotube and activated carbon<sup>[3]</sup>. In this work, RGO decorated on MnO<sub>2</sub> nanoflakes, which are electrochemically deposited on preformed C/TiO<sub>2</sub> shell/core nanowire arrays to form a RGO/MnO<sub>2</sub>/C/TiO<sub>2</sub> shell/core arrays electrode. The electrochemical performance was investigated by cyclic voltammetric measurements, constant current charge/discharge measurements and electrochemical impedance spectroscopic measurements. The RGO/MnO<sub>2</sub>/C/TiO<sub>2</sub> exhibits high specific capacitance of 822.3 F g<sup>-1</sup> at a charge/discharge current density of 1 A g<sup>-1</sup> and 89.3% specific capacitance retained after 1000 cycles. The superior capacitive properties may due to the unique shell/core structure, which can enlarge the electrode/electrolyte contact area and provide more ion adsorption sites for charge-transfer reactions. And the C and RGO layer can provide electron transfer channels, which can provide fast electron transfer for faradic reactions.

Fig. 1 corresponding specific capacitance of RGO/MnO<sub>2</sub>/C/TiO<sub>2</sub> electrode at current density from 1 to 40 A g<sup>-1</sup>(Left) and Impedance Nyquist plots of RGO/MnO<sub>2</sub>/C/TiO<sub>2</sub> electrode(Right).

Electrochemical supercapacitors have been widely investigated over the past few decades because of their increasing use within hybrid electric vehicles, starting assistance of fuel cells, and power sources of electronics. The main challenge in developing advanced supercapacitors for wider applications is to increase the specific energy density, without sacrificing power or life time while keeping low fabrication costs.

Manganese oxide-based materials have been under intense investigation as a pseudocapacitor electrode materials<sup>1</sup>. In this work, sodium doped MnO<sub>2</sub> (denoted as Na<sub>0.33</sub>MnO<sub>2</sub>) was synthesised under aqueous conditions at 75 °C. The microstructure and surface morphologies of Na<sub>0.33</sub>MnO<sub>2</sub> were analysed by powder X-ray diffraction, scanning electron microscopy, Raman spectroscopy, and electrochemical analysis. Cyclic voltammetry (CV) and galvanostatic charge/discharge measurements in a 0.5 M Na<sub>2</sub>SO<sub>4</sub> aqueous electrolyte demonstrated that Na<sub>0.33</sub>MnO<sub>2</sub> exhibits superior rate capability, outstanding capacitance retention, and a high total specific capacitance of 192 F·g<sup>-1</sup> at a current density of 200 A·g<sup>-1</sup>. The excellent rate capability of Na<sub>0.33</sub>MnO<sub>2</sub> is demonstrated by the variation in scan rate of CV from 5 to 1000 mV·s<sup>-1</sup> with 95% capacitance retention when the mass loading of Na<sub>0.33</sub>MnO<sub>2</sub> was increased from 0.5 to 1.0 mg·cm<sup>-2</sup>. Moreover, by increasing the mass loading of Na<sub>0.33</sub>MnO<sub>2</sub> up to 2.0 mg·cm<sup>-2</sup>, the electroactive material possesses a fairly high specific capacitance of 136 F·g<sup>-1</sup> and excellent capacitance retention (81%) as the scan rate is varied from 5 to 500 mV·s<sup>-1</sup>. From these results, Na<sub>0.33</sub>MnO<sub>2</sub> (i.e., Mn oxide pre-intercalated with electrolytic cations) contributes to faster mobility and exchange of cations in the electrolyte. This enables the surface and internal mass of active material to involve the redox transitions in order to provide high pseudocapacitance and outstanding rate capability.

**Fig.** Represents CV's curves in the different potential window from 1.6 to 2.4 V of asymmetric Na<sub>0.33</sub>MnO<sub>2</sub>/activated carbon cell at scan rate of 500 mV·s<sup>-1</sup>.

An aqueous asymmetric supercapacitor with a cell voltage of 2.4 V is demonstrated using activated carbon as the negative electrode and 2.56 mg Na<sub>0.33</sub>MnO<sub>2</sub>/conductive carbon composite as the positive electrode. The specific energy and power of this device (based on total mass of the whole device) measured at 20 A·g<sup>-1</sup> are equal to 5.3 Wh·kg<sup>-1</sup> and 5265 W·kg<sup>-1</sup>, respectively.

Supercapacitors (SCs) have been widely recognized in a wide range of energy storage applications over the past decade, such as hybrid electric vehicles, mobile electronic devices, large industrial equipments, memory backup systems, and military devices. In this current work, a hybrid supercapacitor based on Ni<sub>3</sub>S<sub>2</sub>/multi-walled carbon tube (MWCNT) composite cathode and activated carbon (AC) anode was assembled. The hierarchically structured Ni<sub>3</sub>S<sub>2</sub>/MWCNT composites were synthesized via a facile glucose-assisted hydrothermal method, and the Ni<sub>3</sub>S<sub>2</sub> nanoparticles were homogeneously dispersed on the MWCNT surface. Additionally, the Ni<sub>3</sub>S<sub>2</sub>/MWCNT//AC hybrid supercapacitor can be operated reversibly between 0 and 1.6 V, and obtain a high specific capacitance of 55.8 F/g at 1 A/g, which delivers a maximum energy density of 19.8 Wh/kg at a power density of 798 W/kg. Moreover, 90% retention of specific capacitance was achieved after consecutive 1000 cycles with current density of 4A/g which shows excellent stability. The Ni<sub>3</sub>S<sub>2</sub>/MWCNT//AC hybrid supercapacitor can be viewed as an inexpensive energy storage system.

# Buffer Effect on Electrolytes towards Supercapacitors Application

In this work, we report the effect of addition of buffer on different electrolytes to see the performance of the supercapacitors. The addition of buffer into the electrolyte decrease the difference on the localized pH value around the electrode. The results shows that without addition of buffer solution, the potential window in neutral solution is larger than in acidic or basic solution which contradicts with from thermodynamics prediction. This may due to the localized pH value around the electrode. According to Nernst equation, the potential of hydrogen adsorption and desorption would change along with pH value. So on adding buffer solution into the electrolyte will stabilize the localized pH value around the electrode. In conclusions, adding buffer solution could stabilize the localized pH value around the electrode and the adsorption may shifted towards the earlier potential which correspond to the thermodynamics prediction.

Nickel oxide was formed by electrochemical polarization in 0.5 M KOH using cyclic voltammetry. The upper potential limits of the voltammetric scan controlled the type of oxide namely  $\beta$ -nickel hydroxide ( $\text{Ni}(\text{OH})_2$ ) and  $\gamma$ -nickel oxyhydroxide ( $\text{NiOOH}$ ). The two oxides were formed over a nickel electrode as previously mentioned [1]. Film of graphene oxide was then coated over the surface of the oxide using a microwave technique. The electrochemical behavior of the resulting hybrid film was then studied in different electrolytes. Cyclic voltammetry showed that the anodic current increases with a maximum with four layers of graphene-oxide films are reached with a quasi-reversible behavior in 0.5 M KOH solutions. The electrochemical impedance spectroscopy data proved that the capacitive component of the current increases in the same order.

Surface morphologies of the film formed were studied using atomic force microscopy (AFM) and field emission scanning electron microscopy (FE-SEM). The structure of the film was investigated using surface enhanced Raman spectroscopy (SERS). The data showed that the film is homogeneously distributed over the nickel oxide substrate. The cyclic charge/discharge of the hybrid film was also evaluated. A typical cyclic charging/discharging capacitance diagram is given in the figure. The effect of different types of oxides, number of graphene oxide layers and using different charging current on the charge/discharge behavior was studied.

Figure. Galvanostatic charge/discharge curves of Graphen oxide/ $\text{Ni}(\text{OH})_2$  electrode at a current density of  $2 \text{ mA cm}^{-2}$ . (Capacitance values are not normalized to the mass of the film).

# In-situ Polymerization of Pyrrole in MoS<sub>2</sub> Nanosheets as Highly Conductive Materials with Large Surface Area for Supercapacitors

Chao-Chi Tu, Sheng-Sian Yang, Jun-Ming Chiu, Lu-Yin Lin\*

Department of Chemical Engineering and Biotechnology, National Taipei University of Technology, 1 Sec. 3, Zhongxiao E. Rd., Taipei 10608, Taiwan, R.O.C., E-mail (L. Y. Lin\*): [lylin@ntut.edu.tw](mailto:lylin@ntut.edu.tw)

Supercapacitors (SCs) have attracted much interest due to the potential integration of lithium ion batteries (high energy density) and capacitors (high power density). Molybdenum disulfide (MoS<sub>2</sub>) has been extensively studied as the material for SCs which potentially store charge by intersheet and intrasheet double-layers over individual atomic layers and by faradaic charge transfer processes on the Mo center due to its several oxidation states.<sup>1</sup> Conducting polymers based SCs have received specific attention due to the low cost, broad voltage window, and remarkable storage capacity/reversibility properties. However, direct utilization of bulk conducting polymers as the electrode materials leads to uncontrollable and insufficient exposure of conducting polymers to the electrolytes. By combining the layered transition metal sulfide with conducting polymers, the transition metal centers of metal dichalcogenides can provide strong coordination with nitrogen atoms in conducting polymers, which benefits controllable growth of conducting polymers onto the nanosheet surfaces and offer a uniform and large surface area to immobilize conducting polymers for the charge storage.<sup>2</sup> In this study, two-dimensional MoS<sub>2</sub> nanosheets were synthesized via a simple hydrothermal method, and in turn the conducting polymer, polypyrrole (Ppy), was oxidative polymerized in the solution containing MoS<sub>2</sub> nanosheet in an ice bath to prepare the composites with different ratios of MoS<sub>2</sub> and Ppy. The SEM and TEM images of MoS<sub>2</sub>, Ppy, and the composites with the ratios of 1:0.1, 1:0.5, 1:1, and 1:2 (MoS<sub>2</sub>:Ppy) were shown in **Figure 1**. The layered structure can be obviously observed for the MoS<sub>2</sub>, while the aggregations as well as the outstanding internetworks were found for the Ppy, and for the composites the layered structure can only be clearly obtained for the cases of 1:0.1 and 1:0.5, and for the higher amount of Ppy in the composites (the ratio of 1:1 and 1:2), the nanosheets were hard to be observed. The highest capacitance (182.28 F/g) was obtained for the SC electrode with the composite (ratio of 1:0.5 for MoS<sub>2</sub>:Ppy) as the material, which is higher than those of the SC electrode with MoS<sub>2</sub> (40.58 F/g) and Ppy (116.95 F/g) as the materials as examined using the CV plots (**Figure 2**), due to large charge accumulation surface area provided by the layered structure and the enhanced interconnecting networks given by Ppy for the composite case. The combination of two different classes of the SC material with complementary advantages to achieve the synthetic properties and realized enhanced capacitance is an attractive way to prepared SC with high performance and good cycling life in the future.

**Figure 1** The SEM and TEM images for MoS<sub>2</sub>, Ppy, and composites.

**Figure 2** The CV plots for the SC electrode with MoS<sub>2</sub>, Ppy, and composites as the materials.

# Synthesis of Cobalt Sulfide Hydrangea Macrophylla Nanostructures with High Charge-Accumulation Surface Area for Supercapacitors

Jun-Ming Chiu, Chao-Chi Tu, Sheng-Sian Yang, Cheng-Feng Yu, Lu-Yin Lin\*

Department of Chemical Engineering and Biotechnology, National Taipei University of Technology, 1 Sec. 3, Zhongxiao E. Rd., Taipei 10608, Taiwan, R.O.C., E-mail (L. Y. Lin\*): [lylin@ntut.edu.tw](mailto:lylin@ntut.edu.tw)

Supercapacitors have attracted intense attention due to their features of high specific power density, fast charge and discharge rates, long durability, and environmental friendliness.<sup>1, 2</sup> Transition metal sulfides, *e.g.*, molybdenum sulfides,<sup>3</sup> tungsten sulfides,<sup>4</sup> and cobalt sulfides,<sup>5-7</sup> have been considered as one of the most promising pseudocapacitor electrode materials due to their potential properties of the high specific capacitance and cost effectiveness.<sup>3, 4</sup> In this study, a novel three-dimensional (3D) cobalt sulfide hydrangea macrophylla nanostructure was synthesized by using a simple one-pot method with a post-annealing treatment under the Ar atmosphere. The cobalt sulfide hydrangea macrophylla architectures are constructed by two-dimensional petals intertwined with each other with a thin carbon layer surrounded outside (**Figure 1a** and **1b**). The pseudo-capacitive properties of the cobalt sulfide material are evaluated by cyclic voltammetry (**Figure 2a**) and galvanostatic charge-discharge tests (**Figure 2b**) in a 6 M KOH solution. An extremely high specific capacitance of 1502.09 F g<sup>-1</sup> was obtained for the supercapacitor with the cobalt sulfide hydrangea macrophylla architectures at a charge-discharge current density of 0.5 A g<sup>-1</sup> after optimizing the loading amount (12.5 mg on 1 cm<sup>2</sup>) on the flexible substrate, *i.e.*, Ni foam, due to the large surface area for the charge accumulation and the high conductivity for the charge transfer provided by the 3D hydrangea macrophylla structure and the carbon layer attached outside the petals, respectively. The outstanding supercapacitor performance achieved with this promising hydrangea macrophylla cobalt sulfide therefore opens a window to the establishment of the structure-control techniques for improving the capacitance of the supercapacitors.

**Figure 1** (a) SEM image and (b) TEM image of the hydrangea macrophylla cobalt sulfide.

**Figure 2** (a) The cyclic voltammetry and (b) galvanostatic charge-discharge plot for the hydrangea macrophylla cobalt sulfide electrode with different loading amounts on the Ni foams.

# A Simple Method for Synthesizing Nickel Foam-supported Graphene with High Surface Area for Supercapacitors

Sheng-Sian Yang, Jun-Ming Chiu, Chao-Chi Tu, Lu-Yin Lin\*

Department of Chemical Engineering and Biotechnology, National Taipei University of Technology, 1 Sec. 3, Zhongxiao E. Rd., Taipei 10608, Taiwan, R.O.C., E-mail (L. Y. Lin\*): [lylin@ntut.edu.tw](mailto:lylin@ntut.edu.tw)

Carbon is a kind of novel materials that exists in various structural forms which have been investigated intensively. There is no doubt that hybrid structures composed of different carbon materials can extend the diversity of carbon-based structures, with integrated properties inherited from the constituent structures. However, insufficient surface area of the hybrid films makes them being unable to achieve high loading of electroactive materials and good contact with the electrolyte.<sup>1</sup> The nickel foam-supported graphene has a high surface area and three-dimensional porous architecture, making it have the potential to load more electroactive materials and improving the connection of the carbon and carbon structure to achieve a high electrical conductivity. These advantages make the nickel foam-supported graphene to be suitable for applying on the supercapacitors. Methane is usually used as the carbon precursor to fabricate nickel foam-supported graphene, but its toxic property makes it too dangerous to exhaust.<sup>2, 3</sup> Therefore, in this study, a simple, low cost and environment-friendly method was used to synthesize the nickel foam-supported graphene by a chemical vapor deposition method with the citric acid as the carbon precursor<sup>4</sup> to replace the toxic methane. The SEM images of the pure nickel foam and the nickel foam-supported graphene are shown in **Figure 1a** and **Figure 1b**, respectively. The pure nickel foam is a three-dimensional and porous structure, while few-layer graphene are found to cover on the nickel foam-supported graphene sample, whose surface is much rougher than that of the pure nickel foam.

On the other hand, manganese dioxide has been widely applied as the materials of supercapacitors because of its remarkable theoretical specific capacitance. Unfortunately, its poor conductivity limits its application on the energy storage devices. Therefore, the incorporation of 3D graphene foam as a 3D scaffold and MnO<sub>2</sub> with high theoretical specific capacitance is expected to achieve higher capacitance.<sup>1, 5</sup>

**Figure 1** SEM image of (a) the pure nickel foam and (b) the nickel foam-supported graphene.

# Design and fabrication of supercapacitor electrodes with good rate performance from hole graphene nanosheets

Zong-Huai Liu, Yunlong Bai, Gaini Zhang, Liping Kang, Zhibin Lei

Key Laboratory of Applied Surface and Colloid Chemistry (Shaanxi Normal University), Ministry of Education; School of Materials Science and Engineering, Shaanxi Normal University  
Chang'an Campus: No. 620, West Chang'an Avenue, Chang'an District, Xi'an 710119

Zhliu@snnu.edu.cn

Electrochemical capacitors can bridge the critical performance gap between the energy density of battery and high power density of conventional dielectric capacitor, they make the rapid storage and release of energy become possible [1]. In order to increase the energy density of electrochemical capacitors while retaining their intrinsic high power density, many researchers have focused attention on the development of the new electrode materials with novel structure and morphology. Transition metal nanosheets or graphene nanosheets are new classes of nanoscale materials, they have not only distinctive physicochemical properties, associated with dimensions in the nanometre range, but also large surface area and good electrical conductivity in comparison with their bulk materials [2], and the heterogeneous nanostructured hybrid electrodes having the advantages of transition metal nanosheets with high pseudocapacitance and graphene nanosheets with stable double-layer capacitance can be prepared by a nanosheet reassembling technology. In order to improve the electrolyte transport resistance in the vertical direction, the well-dispersed hole graphene nanosheets are prepared by hydrothermally treating graphene oxide in  $\text{H}_2\text{O}_2$  solution at  $100\text{ }^\circ\text{C}$  for 10 h and followed by refluxing it in  $\text{N}_2\text{H}_4\cdot\text{H}_2\text{O}$  at  $95\text{ }^\circ\text{C}$  for 1 h. The obtained hole graphene nanosheet electrode not only shows superior film-forming property, but also enhances the rate performance. Moreover, the mesoporous-assembled  $\text{MnO}_2$  is prepared by mixing the delaminated  $\text{MnO}_2$  nanosheet slurry and  $\text{NH}_4\text{HSO}_4$  and followed by heating the mixture at  $175\text{ }^\circ\text{C}$ . The optimized electrode shows a specific surface area of  $456\text{ m}^2/\text{g}$ , which gives a specific capacitance of  $281\text{ F/g}$  at a current density of  $0.25\text{ A/g}$ .

**Figure 1.** TEM image of the obtained hole graphene electrode and CV curves at  $200\text{ mV s}^{-1}$  (left) and TEM image of mesoporous-assembled  $\text{MnO}_2$  and the galvanostatic charge-discharge curves at a current density of  $0.25\text{ A g}^{-1}$  (right).

# Nanocrystalline vanadium trioxide as negative electrodes for asymmetric supercapacitors

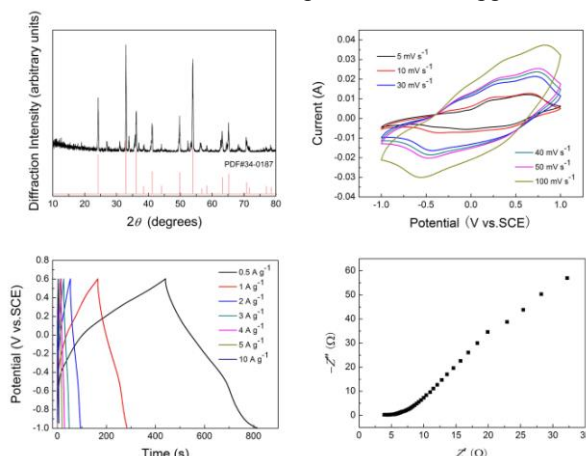

Lingbin Kong<sup>a,b,\*</sup>, Xuejing Ma<sup>a</sup>, Weibin Zhang<sup>a</sup>, Yongchun Luo<sup>b</sup>, and Long Kang<sup>b</sup>

<sup>a</sup> State Key Laboratory of Advanced Processing and Recycling of Non-ferrous Metals, Lanzhou University of Technology, Lanzhou 730050, China. E-mail: konglb@lut.cn

<sup>b</sup> School of Materials Science and Engineering, Lanzhou University of Technology, Lanzhou 730050, China

Among storage devices, supercapacitors are promising due to their combined merits of power density and energy density compared to conventional capacitors and batteries. There are numerous reports on the positive electrode materials with high capacitances working in a wide potential window<sup>[1]</sup>. However, identification of suitable negative electrode is also an imperative one to counter balance the charges and to obtain the superior supercapacitive performance. Among the few negative electrode materials of supercapacitors, vanadium oxides have received significant attention because of their low cost, multiple variable oxidation states and wide potential windows.

Here, a high performance vanadium trioxide negative electrode material was synthesized via a facile strategy of heat treatment and its capacitive behaviour was successfully investigated in a neutral electrolyte. The pseudo capacitive behaviour of the vanadium trioxide was widely researched in 1 mol dm<sup>-3</sup> sodium sulfate aqueous electrolyte using cyclic voltammetry (CV), galvanostatic charge-discharge (GCD) test, and electrochemical impedance spectroscopy. As shown in Fig. 1a, the peaks of vanadium trioxide are in accordance with the reported data (JCPDF card No. 34-0187), revealing the existence of vanadium trioxide phase. Fig. 1b shows the typical CV curves of vanadium trioxide within a potential range of -1.0 V-1.0 V at scan rates of 5 mV s<sup>-1</sup>-100 mV s<sup>-1</sup>. The peak current increases linearly with the increment of the scan rate, which indicated that the kinetics of interfacial Faradic redox reactions and the rates of electronic and ionic transport are rapid enough in present scan rates<sup>[2]</sup>. The CV curves keep the original shape with the increasing scan rates, which indicate the nice ionic and electron conduction of this material. The high specific capacitance (SC) of 118 F g<sup>-1</sup> is achieved at a current density of 0.5 A g<sup>-1</sup> (Fig. 1c). The high SC in the wide potential window and the low diffusion and electron-transfer resistances in the neutral electrolyte of the vanadium trioxide show promise for its application in supercapacitor.

**Fig 1:** a, XRD pattern. b, CV curves. c, GCD curves. d, Nyquist plots of impedance spectra.

For vanadium trioxide, which possesses a 3D V-V framework, its V 3d electrons can itinerate along the V-V chains, leading to metallic behavior. In addition, tunneled structures exist in vanadium trioxide, which facilitates ion intercalation/deintercalation. Therefore, vanadium trioxide is particularly suitable as an electrode material, especially as the negative electrode material in supercapacitors.

# Ordered mesoporous carbon nitride as an electrode material for high performance electrochemical capacitors

Yana Li, Li Wang, Fa-Jun Xia, Tong Yang, Chun-Ling Liu, Wen-Sheng Dong  
Key Laboratory of Applied Surface and Colloid Chemistry (SNNU), MOE, School of Chemistry and  
Chemical Engineering, Shaanxi Normal University, Xi'an, 710062, China  
clliutt@snnu.edu.cn

Although porous carbon materials exhibit large capacitances, the electrical conductivity suffers from a decrease with increasing porosity due to noncompatibility of conductive pathways or oxygen-containing functional groups, which largely limits the power capacity. Besides that, the ionic motion may be hindered in narrow nanopores, which reduces the rate of energy delivery. Thus, the development of carbon materials with high surface area, energy density, specific conductivity properties to improve the power density, and the long cycle life is highly desired.

In this work, the ordered mesoporous carbon nitride (OMCN) with uniform mesopores and a high surface area was synthesized with a nanocasting strategy using hexagonally ordered mesoporous silica SBA-15 as a template. Then, the as-obtained OMCN sample was applied as an electrode for high-performance supercapacitors.

Elemental analysis showed that the as-prepared material contained 16.3% N. Low-angle XRD pattern of the material showed a sharp diffraction peak at  $2\theta \sim 0.9^\circ$  and a weak peak at  $2\theta \sim 1.59^\circ$ , which can be indexed to the (100) and (110) reflections of the two-dimensional (2D) hexagonal (P6mm) structure, respectively. The pattern is similar to the XRD pattern of the parent mesoporous silica template SBA-15, which consists of a hexagonal arrangement of cylindrical pores interlinked by the micropores present in the walls. In the wide-angle region, the OMCN material showed a broad diffraction peak located at  $2\theta$  around  $25^\circ$ , corresponding to the (0 0 2) diffraction of amorphous carbon. The sample featured a type IV isotherm with a H1-shaped hysteresis loop over the  $P/P_0$  range of 0.4–0.8, and narrow pore size distributions, characteristics of highly ordered mesoporous materials. The BET surface area of the material was  $483 \text{ m}^2 \text{ g}^{-1}$ , and the average pore diameter was 4.4 nm.

**Figure 1.** The cycling performance (a) and discharge-charge curves (b) for the OMCN material at different current densities.

The electrochemical measurements of the symmetric supercapacitor were carried out in a two-electrode coin cells at room temperature using 1 M KOH aqueous solution as the electrolyte. The OMCN electrode material showed a specific capacitance of  $223 \text{ F g}^{-1}$  at  $100 \text{ mA g}^{-1}$ , and after 1000 cycles it still remained a specific capacitance of  $218 \text{ F g}^{-1}$ , with a high capacity retention of 97%. At  $1000 \text{ mA g}^{-1}$  the OMCN electrode showed a initial specific capacitance of  $112 \text{ F g}^{-1}$  with a capacity retention of 108%. This electrode material exhibited a specific energy of  $9.6 \text{ Wh kg}^{-1}$  with the maximum specific power of  $28.6 \text{ kW kg}^{-1}$ , which is higher than that of the commercial aqueous capacitors (the power density value is 7~8  $\text{kW kg}^{-1}$ ). The good electrochemical performance of the OMCN material could be attributed to the combined effects of a high nitrogen doping level that changed the electron donor/acceptor characteristics of carbon, improved the wettability of the material in the electrolyte, and the large BET surface area that increased the surface area accessibility for electrolyte ion and enhanced the kinetics of ion and electron transport in electrodes and at the electrode/electrolyte interface.

# **Ni(OH)<sub>2</sub> Nanowires with High Performance as Supercapacitor Electrode via Cathodic Electrodeposition**

Zifan Zeng, Jiliang Zhu, Xiaohong Zhu, Xi Liu, Chuang Kou and Fangyuan Xie

Cross-linked Ni(OH)<sub>2</sub> nanowires was prepared for the electrode materials of supercapacitor via cathodic electrodeposition. The deposition experiments were galvanostatically performed at the current density of 0.5 mA cm<sup>-2</sup> on Ni foam substrate without any surfactant and template. Scanning electron microscopy images indicated that the cross-linked Ni(OH)<sub>2</sub> nanowires were homogeneously distributed on Ni foam with length of 200 nm. The as-prepared Ni(OH)<sub>2</sub> nanowires exhibited ultrahigh specific capacitance of as high as 3637 F g<sup>-1</sup> at the current density of 0.5A g<sup>-1</sup> in the potential window of 0-0.4 V (vs. Ag/AgCl). This result indicates that the Ni(OH)<sub>2</sub> nanowires electrode grown on Ni foam can be considered as a promising candidate for the supercapacitor electrode materials.

# Synthesis and Electrochemical Analysis of Electrodeposited MnO<sub>2</sub>/C Composite Electrode for Supercapacitors

Nobuko Yoshimoto, In-Tae Kim, Nobuo Kouda, and Masayuki Morita  
Graduate School of Science and Engineering, Yamaguchi University,  
2-16-1 Tokiwadai, Ube 755-8611, Japan  
nobuko@yamaguchi-u.ac.jp

Composite materials based on metal oxides and carbon materials have widely been developed as a new route for achieving highly efficient Super capacitors<sup>1)</sup>. A manganese oxide family, typically MnO<sub>2</sub>, is a promising electrode material for electrochemical capacitors due to its low cost, natural abundance, environmental safety and its high theoretical capacitance. However, its low electrical conductivity is a major limiting factor in its electrochemical capacitor application. Such a poor electronic property is usually balanced by the addition of large amounts of conducting carbons like graphite, carbon black, carbon nanotubes, etc. Recently, Nakayama *et al.* have proposed an electrochemical method for preparing thin films of layered manganese oxide by anodic or cathodic synthesis<sup>2, 3)</sup>. They have proposed that the thin films of layered manganese oxide synthesized by the cathodic process exhibited an excellent pseudocapacitive behavior compared with the manganese oxide film grown anodically<sup>3)</sup>. In the present work, we have developed a composite electrode by cathodic deposition of manganese oxide on carbon electrodes with interconnected pores, and have examined its capacitive properties in an aqueous electrolyte solution.

The substrate electrode was prepared by mixing the carbon powder having interconnected pores (CNovel 10 nm, Toyo Tanso), acetylene black, and poly(tetrafluoroethylene). The mass ratio of these materials was 8:1:1. Manganese oxide were deposited on the carbon substrate by applying a constant potential of -0.2 V (vs. Ag/AgCl) in an aqueous solution containing 10 mM KMnO<sub>4</sub> and 250 mM KCl for 30 or 60 min. The deposit was characterized by means of XRD and FE-SEM. Electrochemical behavior of the composite electrode was measured by cyclic voltammetry (CV).

Cyclic voltammograms of the composite electrodes, MnO<sub>2</sub>/carbon, prepared for different polarization times are shown in Fig. 1, compared with carbon substrate electrode, where the measurements were conducted in 0.5 M Na<sub>2</sub>SO<sub>4</sub> solution with the scan rate of 2 mV s<sup>-1</sup>. All electrodes exhibit rectangular-shape voltammograms. The composite electrode prepared for 60 min. (MnO<sub>2</sub>/CNovel (60)) showed the highest current response. The specific capacitances calculated from the current-potential relations were 230 F g<sup>-1</sup> (MnO<sub>2</sub>/CNovel (60)), 172.4 F g<sup>-1</sup> (MnO<sub>2</sub>/CNovel (30)) and 83.5 F g<sup>-1</sup> (CNovel), respectively.

Fig. 1 Cyclic voltammograms of composite electrodes, MnO<sub>2</sub>/carbon, prepared for 30 minutes (a) and 60 minutes (b) in 0.5 M Na<sub>2</sub>SO<sub>4</sub> at the scan rate of 2 mV s<sup>-1</sup>.

Large scale electrical energy storage is receiving increasing world-wide attention because of its potentially important role in enabling a greater fraction of renewable electricity generation and use, and so reducing environmental pollution and climate change. Supercapacitors with high power density and long cycle life are of interest to complement batteries in various applications including transportation and stand-alone or grid-connected renewable power plants. Carbon-based electrodes with organic electrolytes dominate the commercial supercapacitor market. However, they cannot always meet the performance and cost targets for large scale energy storage applications. Therefore research efforts have continued to be focused on improving the performance of supercapacitors, and high capacitances and long cycle life have been achieved in laboratories by many research groups. However, complex synthesis methods and/or expensive raw materials, and non-scalable processing are often used to obtain this performance, which may not only restrict large-scale production, but also have unattractive cost implications.

Mill scale is a waste product from the steel industry and is composed of various iron oxides/hydroxides. This paper studies the supercapacitive behavior of mill scale received directly from a large steel plant, and after various cheap and scalable physical and chemical treatments. Techniques of cyclic voltammetry, charge/discharge and electrochemical impedance spectroscopy are used. The paper describes how, starting from intriguing but insufficient storage capacity, the mill scale can be readily manipulated and processed to produce a range of chemistries and morphologies. Ball milled mill scale with a specific capacitance of 92 F/g at a scan rate of 5 mV/s in Na<sub>2</sub>SO<sub>3</sub> electrolyte was transformed to different oxides using simple heat treatments, reaching 137 F/g, again at 5 mV/s in the same electrolyte. Then following further simple treatments, a capacitance of 240 F/g at a scan rate of 5 mV/s or 236 F/g at a discharge current density of 2 A/g was maintained at over 90% for 1,000 cycles. At each stage the chemical changes in the materials are described in detail, and the mechanisms for the progressive increases in performance discussed. Finally the future prospects for supercapacitors based on the scalable and low-cost processing of plentiful mill scale waste is presented.

# Electrochemical Co-deposition of Polyaniline with Inorganic Oxides for Pseudocapacitive Application

Xiao-Xia Liu, Li-Jie Sun, Ming-Hua Bai  
 Department of Chemistry, Northeastern University  
 3-11 Wenhua Road, Shenyang, 110819, China  
 xxliu@mail.neu.edu.cn

Pseudocapacitor is emerging as a new class of charge storage device with higher energy density compared to electrical double-layer capacitor. Conducting polymers and inorganic oxides have promising applications in pseudocapacitor due to their high specific capacitance compare to carbon materials. Their composites, especially nanocomposites, have special advantages due to the combined merits and synergistic effects of organic and inorganic components.

Polyaniline (PANI) has promising applications in pseudocapacitor. One-dimensional (1D) growth control of PANI has aroused great interest because an ordered arrangement of the polymer chains favours higher conductivity and better performance in applications. Although 1D growth is known to be intrinsic to PANI, heterogeneous nucleation on the initially-formed 1D PANI would result in irregularly-shaped PANI particles. 1D growth control of PANI through electrochemical co-deposition with inorganic oxides is a good way to fabricate 1D organic-inorganic composite through the suppression of this overgrowth on the surface active sites of initially-formed 1D PANI.

In this work, we will present the 1D growth control of PANI through electrochemical composition with inorganic oxides. Incorporation of oxide nanoparticles on the polymer chains was first conducted through electro-co-polymerization of aniline and *N*-substituted aniline grafted on surfaces of oxide nanoparticles to avoid the chain entanglement by electrostatic repulsion between positive charged oxide nanoparticles (Fig. 1).

Fig. 1 (a) Schematic of incorporation of oxide nanoparticle onto PANI chain via triethoxysilylmethyl *N*-substituted aniline (ND); (b) SEM images of the obtained composite of PANI-ND-MnO<sub>2</sub>.

The local environment at the electrode surface for aniline polymerization was also tried to be controlled by the electrodeposition of inorganic oxides from their precursors like VO<sup>2+</sup> and Mn<sup>2+</sup>, in which process proton may be released and some of the anodic charges may be consumed to control the amount of the charge for aniline polymerization. 1D growth of PANI was successfully conducted to afford PANI based nanocomposites with improved pseudocapacitive properties (Fig. 2).

Fig. 2 (a) SEM images of PANI-VO<sub>x</sub> composite; (b) discharge profiles of PANI, VO<sub>x</sub> and PANI-VO<sub>x</sub>.

Global climate warming and environment pollution have spurred scientists to develop new high-efficient and environmental-friendly energy technologies. Hydrogen is an ideal fuel for fuel cell applications. Hydrogen has to be produced from renewable and carbon-free resources using nature energies such as sunlight if one thinks of clean energy and environmental issues. In this regard, a photoelectrochemical (PEC) cell consisting of semiconductor photoelectrodes that can harvest light and use this energy directly for splitting water is a more promising way for hydrogen generation. Abundant and inexpensive oxide semiconductor such as ZnO has been recognized as a promising photoelectrode, but the photoconversion efficiency is substantially limited by its large band gap and rapid charge recombination. Recently, doping with 4d transition metal, such as Mo, has been carried out to remarkably enhance the PEC performance of many photoanodes including TiO<sub>2</sub>, BiVO<sub>4</sub>, and Fe<sub>2</sub>O<sub>3</sub>. Nevertheless, 1-D Mo-doped ZnO nanostructures have not been reported for PEC water splitting. We report the first demonstration of cobalt phosphate (Co-Pi) assisted Zn<sub>1-x</sub>Mo<sub>x</sub>O nanorods (NRs) as visible-light-sensitive photofunctional electrodes to fundamentally improve the performance of ZnO NRs for PEC water splitting. The maximum photoconversion efficiency could be successfully achieved as high as 1.05%, with the significant photocurrent density of 1.4 mA cm<sup>-2</sup>. More importantly, in addition to achieve the maximum incident photon to current conversion efficiency (IPCE) value of 86%, it could be noted that the IPCE of Zn<sub>1-x</sub>Mo<sub>x</sub>O photoanodes at the monochromatic wavelength of 450 nm is up to 12%. Our PEC performances are comparable to those of many oxide-based photoanodes in recent reports. The improvement in photoactivity of PEC water splitting may be attributed to the enhanced visible-light absorption, increased charge-carrier densities, and improved interfacial charge-transfer kinetics due to the synergistic effects of Mo incorporation and Co-Pi modification, thus contributing to photocatalysis. The new design of constructing highly photoactive Co-Pi assisted Zn<sub>1-x</sub>Mo<sub>x</sub>O photoanodes enriches the doping community and sheds light on developing high efficiency photoelectrodes for solar-hydrogen field.

\*E-mail: kcho@ntu.edu.tw

In dye-sensitized solar cells (DSSCs), platinum (Pt) is the most used catalyst as the counter electrode (CE) because of its high conductivity, stability and electrocatalytic activity toward I<sub>3</sub><sup>-</sup>/I<sup>-</sup> redox reaction. However, the high cost and energy-consuming fabrication process of the Pt CE limits its applicability. Two-dimensional (2D) molybdenum diselenide nanosheets, an earth-abundant compound, have been recently demonstrated as a promising material for the application in photovoltaic devices and electrocatalytic systems. With the incorporation of water-dispersible conducting polymer, poly(3,4-ethylene dioxithiophene): poly(4-styrene sulfonate) (PEDOT:PSS), we successfully synthesized MoSe<sub>2</sub>/PEDOT:PSS composite CEs via a facile fabricating route for use in Pt-free DSSCs.

In this study, a composite film containing MoSe<sub>2</sub> and PEDOT:PSS was deposited on fluorine-doped tin oxide (FTO) substrate by a drop-coating method. Three kinds of catalytic films of PEDOT:PSS, MoSe<sub>2</sub>, and MoSe<sub>2</sub>/PEDOT:PSS composite were investigated as the CEs for DSSCs. After the optimization of composition and thickness of the MoSe<sub>2</sub>/PEDOT:PSS composite film, a light-to-electricity conversion efficiency ( $\eta$ ) of 7.58% was achieved for the pertinent DSSC, which was found to be higher than those of cells with bare PEDOT:PSS (2.90%) and bare MoSe<sub>2</sub> (2.29%), and this efficiency (7.58%) is also comparable to that of the cell with a sputtered-Pt CE (7.81%, in Fig. 1). The catalytic ability and electrochemical properties of the CEs were quantified by cyclic voltammetry (CV) (Fig. 2), electrochemical impedance spectroscopy (EIS) (Fig. 3), and Tafel plots (Fig. 4). These measurements suggest that the superior performance of the DSSC with a MoSe<sub>2</sub>/PEDOT:PSS CE, as compared to those with either bare PEDOT:PSS or bare MoSe<sub>2</sub> CEs, is mainly attributed to its better electrocatalytic activity and lower charge transfer resistance toward the I<sub>3</sub><sup>-</sup> reduction reaction.

deak@bccms.uni-bremen.de*

The synergic effect of mixing rutile (R) and anatase (A) crystals in photocatalysis is often attributed to a staggered alignment of the band structures, but it is widely disputed whether the conduction band edge of rutile or that of anatase is higher. Photoelectron spectroscopy (PES) supports the former, flat-band potential (FBP) measurements the latter. Theoretical alignment of the bulk band structures, as well as calculated offsets across actual interfaces support the PES data. The theoretical study presented here shows that the FBP data can be explained by taking into account the adsorption of free OH<sup>-</sup> and H<sup>+</sup> ions in the electrolyte. We conclude that in case of sintered nano-powders, applied in actual photocatalysis, the dipole layer created by surface adsorption and the one at the R/A interface both have an influence on the alignment, and the end result may change from experiment to experiment.

# **Solution-Processed Nanostructured p-type Photocathodes for Solar Hydrogen Production**

High-efficiency solar-to-fuel energy conversion can be achieved using a photoelectrochemical (PEC) device consisting of an n-type photoanode in tandem with a p-type photocathode. However, the development of stable and inexpensive p-type photocathodes are needed to make PEC devices economically viable. In this presentation our group's progress in the development of economically-prepared, high performance photoelectrodes will be discussed along with the application toward overall PEC water splitting tandem cells. Specifically, how the use of scalable solution-processing techniques (e.g. colloidal processing of nanoparticles or sol-gels) leads to limitations in charge transport and charge transfer in the resulting thin-film photoelectrode will be examined. Strategies to overcome these limitations such as using charge extraction buffer layers, catalysts, annealing/doping and nanoparticle self-assembly will be additionally presented. Materials of interest are delafossite  $\text{CuFeO}_2$ , CZTS, CIGS, CdS and 2D-layered  $\text{MoS}_2$  and  $\text{WSe}_2$ .

It's widely accepted that carbon dioxide accounts for the largest share of the anthropogenic greenhouse-gas emission. Not only the reduction of fossil-fuel consumption, but also CO<sub>2</sub> capturing and sequestration are needed to counter the inevitable threat. Unfortunately, most of the thermochemical processes for CO<sub>2</sub> valorization require extraneous energy input, which may result in the net growth of CO<sub>2</sub> emission. In this regard, photocatalytic conversion of CO<sub>2</sub> to hydrocarbons under solar excitation becomes a viable approach, to solve the energy and environmental crisis by recycling CO<sub>2</sub> to fuels. Bio-mimetic processes based on photosynthesis allowing simultaneous solar energy harvesting and CO<sub>2</sub> reductions thus become highly desirable. In this work, systematic investigation of GO for photocatalytic CO<sub>2</sub> reduction process has been performed based on various GOs synthesized in different conditions. Quantitative and qualitative determinations of the methanol formation have performed by Gas chromatography (GC) and Gas chromatography–mass spectrometry (GC-MS). Photocatalytic conversion of carbon dioxide (CO<sub>2</sub>) to hydrocarbons such as methanol makes possible simultaneous solar energy harvesting and CO<sub>2</sub> reduction, two birds with one stone for the energy and environmental issues. This work describes a high photocatalytic conversion of CO<sub>2</sub> to methanol using graphene oxides (GOs) as a promising photocatalyst. Modified Hummer's method has been applied to synthesize the GO based photocatalyst for the enhanced catalytic activity. Further, Cu and MoS<sub>2</sub> nanoparticles and were deposited on GO as co-catalysts to enhanced the photocatalysis reaction. Not only methanol, but also acetaldehyde were detected. Total solar to fuel yield of 6.8 mole g-cat-1 h-1 have been achieved, which is 240 times enhancement relative to the commercial P-25 photocatalyst. Detailed preparation and characterization of the catalysts will be addressed.

Photoelectrochemical water splitting has gathered significant attention in recent years as a very promising process for the sustainable generation of hydrogen. In a common photoelectrochemical cell design, either one or both electrodes contain semiconducting materials that, when exposed to light, generate charge carriers that can catalyze the water splitting reaction. While surface-structured photoelectrodes have consistently shown better performance, in most studies the structuring geometry is a byproduct of the material synthesis process. As a result, there is very limited control of the final surface structuring, and it is difficult to explore structure-property relationships.

We are employing nanoimprint lithography for the systematic fabrication of structured photoelectrodes with precisely defined surface structuring geometry. The resulting model systems are being used to investigate the influence of surface geometry on photoelectrochemical performance. For our initial model systems we have selected highly doped silicon as a substrate material. The choice of nanoimprint mold determines the dimension of the surface structuring features, while the final geometry and aspect ratio can be controlled by the etching parameters. The substrates are finally coated with TiO<sub>2</sub> and WO<sub>3</sub> by atomic layer deposition. The structured electrodes are extensively characterized in order to correlate structure to physicochemical properties and electrocatalytic performance in the water splitting reaction.

Figure 1. Incident photon-to-current efficiency (IPCE) of a photoanode prepared by ALD deposition of TiO<sub>2</sub> on n-Si (AM1.5G, H<sub>2</sub>SO<sub>4</sub> 0.5 M). Inset: SEM cross-section of structured n-Si substrate.

Hydrogen is the simplest solar fuel to produce and in this presentation we shall give a short overview of the pros and cons of various tandem devices [1,2]. The large band gap semiconductor needs to be in front, but apart from that we can choose to have either the anode in front or back using either acid or alkaline conditions. Since most relevant semiconductors are very prone to corrosion the advantage of using buried junctions and using protection layers offering shall be discussed [3-5]. In particular we shall show how doped TiO<sub>2</sub> is a very generic protection layer for both the anode and the cathode [6]. Next we shall discuss the availability of various catalysts for being coupled to these protection layers and how their stability and amount needed may be evaluated [7, 8, 9]. Examples of half-cell reaction using protection layers for both cathode and anode will be discussed though some of recent examples both under both alkaline and acidic conditions. Notably NiO<sub>x</sub> promoted by iron is a material that is transparent, providing protection, and is a good catalyst for O<sub>2</sub> evolution [10]. Si is a very good low band gap semiconductor and the optimal thickness of this in a tandem device will be discussed [11]. We have also recently started searching for large band gap semiconductors like III-V based or perovskite materials and follow the same strategy by using protection layers and catalysts [12]. Finally if time allows we shall also discuss the possibility of making high energy density fuels by hydrogenation of CO<sub>2</sub> instead of hydrogen evolution [13].

In the research field of electrochemical solar cells, dye-sensitized solar cells (DSCs) have a hard time because perovskite solar cells have made new record of photochemical solar cells. Its efficiency increase is very precipitous. The efficiency which started from 3.8% in 2009 already exceeded 20%. However, perovskite solar cells have hysteresis problem and poor stability despite high performance. On the other hand, DSC is chemically and physically more stable and it is still attractive and competitive. Low manufacturing cost is one of its strong points. However, expensive materials such as Pt and transparent conductive electrode are still used in DSCs. Especially, Pt is a still dominant counter electrode material from initial stage in 1991 although various materials such as carbon, graphene, and polymer have been studied as counter electrode so far. Here, we studied on low cost polymer counter electrode for replacing Pt. Polymer counter electrode was based on poly(3,4-ethylenedioxythiophene):poly(4-styrenesulfonate) (PEDOT:PSS). Its insufficient catalytic reaction significantly decreased fill factor, resulting in low initial performance of DSC. In order to improve catalytic characteristics of polymer counter electrode, PEDOT:PSS layer was surface-modified by nano-particle addition. PEDOT:PSS was deposited on the counter electrode by spin-coating. Flat PEDOT:PSS layer with RMS of 10nm had small surface area and its catalytic reaction was limited. On the other hand, surface-modified PEDOT:PSS layer had enhanced catalytic characteristics with increased surface area. This catalytic activation supplied more electrons into electrolyte than Pt counter electrode and fill factor was much increased. Consequently, overall performance was also enhanced. We tried to investigate various nano-particle materials such as TiO<sub>2</sub>, ZnO, SiO<sub>2</sub>, ZrO<sub>2</sub> and so on. We arranged the effect of various nano-particles in this work and a DSC with improved PEDOT:PSS counter electrode had finally higher performance than a standard DSC with Pt counter electrode.

# Efficient sunlight-driven reduction of CO<sub>2</sub> to fuels based on Cu<sub>2</sub>O and perovskite absorbers

CO<sub>2</sub>-derived fuels present an attractive way towards a sustainable energy system. Mimicking natural photosynthesis by synthesizing carbon based energy carriers using power from the sun allows for closing the anthropogenic carbon cycle and therefore represents an attractive way to store solar energy, a challenge which has not yet found a satisfying solution.

Our group pursues this goal from two angles. In one approach, we demonstrate the photoelectrochemical conversion of solar energy to CO, based on concepts which integrate light absorption and catalysis in a single device. In the second angle, we are exploiting the high open circuit voltage supplied by perovskite solar cells to achieve the unassisted conversion of CO<sub>2</sub> to CO with record efficiency.

Solar irradiation is the only source of energy of sufficient magnitude to replace fossil fuels. Its widespread use will, however, require very large surfaces of absorbers, which should therefore be fabricated from abundant and low cost materials. Here, we show the application of low-cost and scalable Cu<sub>2</sub>O photocathodes in combination with molecular rhenium catalysts, both in solution [1] and, as an extension of this work, molecularly grafted to the photoelectrode surface (Figure 1). From both approaches we observe large photocurrents and photovoltages, demonstrating protected Cu<sub>2</sub>O photocathodes as viable candidates for solar-driven CO<sub>2</sub> reduction processes. Investigating the charge transfer behaviour on these systems allows us to observe unexpected effects which provide new insight into the mechanism of Re-based CO<sub>2</sub> reduction catalysts.

Another type of low-cost solar absorber having attracted significant interest in recent years are CH<sub>3</sub>NH<sub>3</sub>PbI<sub>3</sub>-based solar cells. [2] In addition to achieving very high power conversion efficiencies, these devices exhibit large open circuit photovoltages, making them particularly suitable for water splitting and CO<sub>2</sub> conversion processes. Using these devices, our group has recently demonstrated the highly efficient conversion of solar energy to hydrogen with 12.3% efficiency. [3] Here, by combining series-connected perovskite solar cells with highly efficient electrocatalysts, we take this approach further to demonstrate the efficient splitting of CO<sub>2</sub> to CO and O<sub>2</sub> with record efficiencies exceeding 6.5%, using sunlight as the sole source of energy (Figure 2). [4] This approach is further being pursued towards the use of novel and low-cost nanostructured catalyst fabrication processes, which will also be presented.

Figure 1: Schematic of the photoelectrochemical conversion of CO<sub>2</sub> on the surface of protected Cu<sub>2</sub>O photocathodes.

Figure 2: Schematic (left) and J-V curves (right) for the perovskite-driven photolysis of CO<sub>2</sub>.

Compact film of dye-sensitized solar cells (DSSCs) also as known as passivation layer or blocking layer, is formed over the conductive layer of glass prior to the oxide paste printing or coating, and is crucial to inhibit the electron back reaction. There are some physical routes to form perfect compact film such as the magnetron sputtering and atomic layer deposition. However, for a low-cost process as well as the flexible ploymeric substrates consideration, low-temperature process has some advantages over those physical ways. The conductive glass treated with dilute  $\text{TiCl}_4$  solution is widely used a wet chemical route to form compact film of DSSCs, but it is not stable enough and releases  $\text{HCl}$  during drying and subsequently annealing process. We presented some less reactive precursors such as aqueous anatase  $\text{TiO}_2$  sols [1], soluble and neutral titanium (IV) bis (ammonium lactato) dihydroxide [2], to form compact film via spinning coating, dip coating, spray coating as well as self-assembly [3]. In this paper, the less reactive precursor  $(\text{NH}_4)_2\text{TiF}_6$  solution [4] was used to fabrication compact film via liquid phase deposition, and very dense anatase  $\text{TiO}_2$  film where the crystallite size was less than 9 nm were deposited over FTO glass at temperature above 60 °C. Some novel technique such as all-semiconductor self-assembly (ASSA) was also presented to form compact film using various oxide colloids and compared with each other. The energy conversion efficiency ( $\eta$ ), fill factor, electrochemical impedance spectroscopy (EIS) were characterized to evaluate the DSSCs performance in the presence of compact film and in some cases an 20% increment of  $\eta$  was observed. The charge recombination resistance at  $\text{TiO}_2/\text{dye}/\text{electrolyte}$  interface was significant reduced in the presence of chemical route derived compact film, as verified with EIS.

# Photoelectrochemical Zero Bias Hydrogen Generation with a Novel Three Compartment Cell for Decreasing Theoretical and Total Water Electrolysis Voltage (10)

Kenji Sakamaki, Ryoko Kato, Haruka Endo, Masataka Sato, Yoichi Kamo  
Department of Chemistry, Fukushima College, National Institute of Technology (FC-NIT)  
Iwaki, Fukushima 970-8034, Japan  
sakenji@fukushima-nct.ac.jp

The first successful electrochemical photolysis of water reported by Fujishima and Honda in 1972 is a milestone in the history of advanced hydrogen generation [1, 2]. We have developed a novel three compartment cell with a combination of cation (basic) and anion (acidic) exchange membranes (electrolytes) bridging a neutral electrolyte. The three compartment cell generates internal bias induced by a proton concentration gradient, chemical bias, leading to a decrease of theoretical and total water electrolysis voltage for hydrogen generation [3-5].

The onset potential for hydrogen generation is only 1 V with two Pt electrode system in three compartment cell [3]. To extend the above concept, electrochemical water splitting voltage would be significantly decreased with much lower oxygen overpotential alternatives than Pt. Using dimensionally stable anode Ti or Pt/RuO<sub>2</sub>-IrO<sub>2</sub> (Permelec electrode, DeNorra), Ni or Fe in basic compartment cell and Pt in acidic compartment cell, we have accomplished the onset potential of 0.7-0.8 V for hydrogen evolution.

Photoelectrochemical (PEC) zero bias hydrogen generation has already been achieved with self-assembled nanoarchitecture anatase TiO<sub>2</sub> anode in three compartment cell [3-5]. We call this system fuel type (acid-base) PEC zero bias hydrogen generation or water splitting. The net charges are zero in all three solutions in compensation for photoinduced charge separation, leading to an efficient hydrogen generation. Tandem-cell designed to combine a visible light responsive photoelectrode with the chemical bias is performed with Fe(III) oxygen evolving catalyst crafted on Fe<sub>2</sub>O<sub>3</sub> hematite anode being stable in basic solution [6, 7]. We have succeeded in measuring a visible light zero bias photocurrent for hydrogen generation. Our finding is beneficial to the crucial prerequisite for hydrogen economy, environmentally benign large-scale low cost hydrogen production.

marketa.zukalova@jh-inst.cas.cz

Compact TiO<sub>2</sub> thin films are used as blocking layers in solid state dye sensitized solar cells (DSCs), and in the perovskite solar cells. Here, the TiO<sub>2</sub> film serves as an electron collector and simultaneously as a buffer layer, preventing recombination of photoexcited electrons from the substrate, typically F-doped SnO<sub>2</sub> conducting glass (FTO) with the hole conductor[1]. The compact TiO<sub>2</sub> film is grown on top of FTO, usually by spray pyrolysis, DC-magnetron sputtering, electrochemical deposition, atomic layer deposition and spin coating. Recently, we developed facile sol-gel dip coating technique producing dense and extremely mechanically stable TiO<sub>2</sub> thin films on various substrates from precursor solutions containing poly(hexafluorobutylmethacrylate) or hexafluorobutyl methacrylate as the structure-directing agents[2]. The films are quasi-amorphous, but crystallize to TiO<sub>2</sub> (anatase) upon heat treatment at 500°C. Blocking properties of the films were tested by cyclic voltammetry using Fe(CN)<sub>6</sub><sup>3-/4-</sup> in aqueous electrolyte solution as the model redox probe[3]. The same test was repeated by spiro-OMeTAD in dichloromethane electrolyte solution. The as-grown films can produce an excellent rectifying interface with almost no pinholes, however, defects are created upon heat treatment at 500°C in air, when anatase crystallization occurs. The overall area of thermally induced pinholes is comparable to that in spray-pyrolyzed titania films. The flat-band potentials,  $\phi_{FB}$  of the as-grown films are upshifted by about 0.2–0.4 V against the values predicted for a perfect anatase single-crystal surface, but they still follow the Nernstian pH dependence. Proton insertion into titania takes place during electrochemical n-doping in aqueous acidic electrolyte solution at sufficiently negative potential[4]. The good-quality films are ideally compact, mimicking the properties of a macroscopic single crystal electrode. In contrast to porous polycrystalline electrodes, the doping of our dense films persists for at least weeks, if the electrode is stored in air at room temperature. Doping manifests itself by permanent color changes and by characteristic morphological differences on the surface. The doped films still accommodate Li<sup>+</sup> by electrochemical insertion, but competition between Li<sup>+</sup> and H<sup>+</sup> ions in the lattice is detected by cyclic voltammograms.

# An Organic Semiconductor as a Photoanode for Solar Water Splitting

Pauline Borno, Mathieu Prévot, Xavier Jeanbourquin and Kevin Sivula

*Institute of Chemistry and Chemical Engineering, École Polytechnique Fédérale de Lausanne, Station 6  
1015 Lausanne Switzerland  
pauline.borno@epfl.ch*

For the past 30 years, photoelectrochemical cells (PEC) have held promise as an inexpensive route to convert renewable solar energy into chemically stored energy (solar fuels) on a scale suitable for the world energy demand. Indeed the use of solar fuel offers a decentralized and constant energy flux insensitive to daily or seasonal variation. A solar-to-hydrogen (STH) efficiency of over 20% has been shown to be theoretically feasible when using a PEC tandem cell for water-splitting and cells with high efficiency have been demonstrated, however the materials and fabrication are too expensive to compete with hydrogen production via standard photovoltaic devices in combination with electrolyzes. This has motivated a search for new materials that can offer high performance, but also low device cost. In the last decade, an emerging field of organic semiconductor materials has attracted much attention for solar photovoltaic devices due to their optoelectronic versatility and ability to be processed by solution based roll-to-roll techniques. Despite their popularity only a few reports have investigated these materials for solar water splitting due to their low stability in the harsh operating conditions.

In this work we demonstrate the successful use of a bare conjugated organic material as a photoanode for solar water splitting. Poly(benzimidazobenzophenanthroline) (BBL) n-type material was selected due to its rigid ladder-type backbone offering high stability in an aqueous environment and high thermal stability. A dispersion-assisted spray deposition technique was designed to overcome processing difficulties with this rigid, poorly-soluble material and the preparation of large-area of homogeneous films with controllable thickness is demonstrated. Optical and morphological characterization of the films performed by UV-vis measurement and scanning electron microscopy show very good absorption characteristics covering a broad range of the visible spectrum and a microporous morphology. Determination of the band gap at 1.86 eV and position of LUMO/HOMO level shows adequate energy position for its use as a photoanode in a tandem cell. The film was further characterized by electrochemical measurements (J-V curve under chopped light, cyclic voltammetry and impedance spectroscopy) and a photocurrent of 0.2 mAcm<sup>-2</sup> at 1.23 V vs. RHE was observed under standard illumination conditions in aqueous electrolyte with a sacrificial electron donor. Possible use for water oxidation is subsequently demonstrated in aqueous electrolyte with the direct observation of OH radical product. Mott-Schottky analysis reveals the independence of the flat band potential with respect to pH of electrolyte. Different surface treatments were finally investigated to reduce kinetics limitations for water oxidation and the direct production of molecular O<sub>2</sub> from water oxidation was observed.

Cathode in classical dye-sensitized solar cell (DSC) is usually a platinized F-doped SnO<sub>2</sub> (FTO) which, however, contributes by about >20-60% to the cost of the DSC-module. The search for cheaper cathode materials points at nanocarbons and graphene-based materials, particularly for Co-mediated DSCs.[1,2] Another alternative, which also works well with the I<sub>3</sub><sup>-</sup>/I<sup>-</sup> redox mediator, is the woven fabric consisting of transparent PEN fibers in warp and electrochemically platinized tungsten wires in weft.[3] (Patented by Sefar AG: Peter Chabreck et al., European Patent Specification EP 2 347 449 B1, published 25.03.2015.) This electrode outperforms the platinized FTO in serial ohmic resistance,  $R_s$  (1.5 vs. 8.2  $\Omega\text{cm}^2$ ), charge-transfer resistance for triiodide reduction (0.59  $\Omega\text{cm}^2$  vs. 0.76  $\Omega\text{cm}^2$ ) and offers comparable or better optical transparency in the visible and particularly in the near-IR spectral region ( $\approx 80\%$ ). The Pt-W/PEN cathode exhibits good stability during electrochemical load with the maximum (diffusion-limited) current both in cathodic and anodic directions, and during long term ( $\approx$ months) storage at open circuit. The practical dye-sensitized solar cells with either Pt-W/PEN or Pt-FTO cathodes show similar performance, confirming that the former is a promising alternative for replacement of conductive glass in the DSC cathodes. In the field of p-DSCs (with sensitized photocathode) the generic semiconductor material is p-NiO. An alternative p-semiconductor is B-doped nanodiamond which offers excellent chemical and electrochemically stability, optical transparency and favorable electrical properties. The electrochemical inertness of BDD is beneficial in view of the corrosive nature of certain electrolyte solutions used in DSCs. Spectral sensitization of nanodiamond was carried out by anchoring of dyes like 4-(bis-{4-[5-(2,2-dicyano-vinyl)-thiophene-2-yl]-phenyl}-amino)-benzoic acid (P1 from Dyenamo AB) with polyethyleneimine as a linker. The sensitized diamond exhibits stable cathodic photocurrents under visible light illumination in aqueous electrolyte solution with dimethylviologen serving as electron mediator.[4] In spite of the simplicity of the surface sensitization protocol, the photoelectrochemical performance is similar or better compared to that of other sensitized diamond electrodes which were reported in previous studies.[5]

# Plasmon-Induced Efficiency Enhancement on Dye-Sensitized Solar Cell by a 3D TNW-AuNP Layer

Kuan-Jiuh Lin, Yin-Cheng Yen

Department of Chemistry, National Chung Hsing University  
250, Kuo Kuang Road, Taichung 402, Taiwan, R.O.C.  
kjlin@dragon.nchu.edu.tw

It is well known that the narrow absorption wavelength and low absorption coefficient of N719 dye is a major problem which limits the development of DSSCs. In order to overcome this problem, we propose a new type of plasmonic functionalized electrodes (PFEs) which can be used in different dye-absorbed DSSCs to enhance light harvest and cell efficiency by either antireflective (AR) properties of TNWs or/and plasmonic effect of Au nanoparticles (NPs). A remarkable plasmonic red-shift from 520 nm to 575 nm was observed in Au (11 nm). It was attributed that Au NPs have a specific bonding interaction with TNWs and plasmonic electrode exhibit a strong localized electric field. We demonstrated a 55.68% improvement in the case of  $\text{TiCl}_4$  treated Au (11 nm). The aforementioned superior PV performance achieved herein is mainly attributed to localized electric field improvement by plasmonic collective coupling effect within this favorable TNW-AuNP hybrid nanostructures. Moreover, the fabrication technique of PFEs is inexpensive, simple, and can easily be scaled up which is suitable for mass production. We believe new type of PFEs will beyond the current record of efficiency after optimization. Also, PFEs may open up numerous possibilities for the use of organic solar cells, electric photocatalysts and water splitting components.

Conducting polymer-based hole conductors (HCs), directly deposited into the mesoporous structure of dye-coated TiO<sub>2</sub> electrodes by *in-situ* photoelectrochemical polymerization (PEP) method, have the advantage of easy penetration and uniform pore infiltration compared to small molecular HCs used in solid-state dye-sensitized solar cells (sDSCs). The aforementioned advantages of conducting polymer-based HCs generated by PEP would lead to an efficient charge separation at the TiO<sub>2</sub>/dye/HC interface. Besides, instead of the additional chemical doping for small-molecule HCs, the remarkably high hole conductivity of conducting polymer HCs resulting from *in-situ* electrochemical doping in PEP could provide a high charge collection yield in devices, making it a competitor to the usual alternatives, redox mediator-containing liquid electrolytes or small-molecule HCs, as dye solar cell charge-transport media.<sup>[1]</sup>

The present work is directed toward the study on how the parameters in PEP affect the physicochemical properties of the formed conducting polymer and, consequently, the corresponding solar cell performance. At first, an aqueous micellar electrolyte, instead of the usual organic solution, was demonstrated for the first time to be possible to use as PEP medium to generate PEDOT HC from *bis*-EDOT precursor.<sup>[2]</sup> The advantage of aqueous PEP over organic PEP is not only the fact that the process is inexpensive and environment-friendly character of the process, but also that the oxidation potentials of the precursor in aqueous solution is less positive, resulting to an increased driving force for PEP. The sDSCs based on PEDOT generated from aqueous PEP show a solar-to-electrical power conversion efficiency (PCE) of 5.2% with an organic sensitizer, as compared to 5.6% for similar devices based on organic PEP.<sup>[3]</sup> By comparison of the PEDOT properties for layers generated from the two approaches, a PEDOT variety with shorter polymer chains was obtained in aqueous PEP, as corroborated by matrix-assisted laser desorption mass spectrometry, resulting to better dye regeneration, but also to faster charge recombination in the devices.<sup>[4]</sup> A second direction of work is to use the less expensive precursor (monomer) EDOT as precursor to replace *bis*-EDOT. The PEP of EDOT was first time achieved in aqueous electrolyte due to the much lower oxidation potential than that in organic solution, where PEP is difficult; the corresponding sDSCs exhibit 3.0% efficiency.<sup>[5]</sup> Thirdly, an alternative monomer, 3,4-ethylenedioxythiophene (EDOT), was efficiently used in PEP by combining with organic metal-free charge-transfer (Donor- $\pi$ -Acceptor) dyes. The devices based on the PEDOT hole conductor have a PCE of 4.5%; this level of performance, achieved for the first time for PEDOT-based sDSCs, is attributed to the high hole conductivity of PEDOT and the good blocking effect from organic dyes;<sup>[6]</sup> At last, the importance of the dyes' chemical structure and energy levels on the PEP has been systematically investigated. It is shown that, on one hand, the dyes' blocking effect variations, due to the different chemical structure, play a significant role on the interfacial charge recombination; on the other hand, the redox potentials of the dyes could affect the kinetics of the PEP process and the final polymer properties. By effectively combination of an organic D- $\pi$ -A dye LEG4 and the formed PEDOT HC, a PCE of 7.1% with a record current (13.4 mAcm<sup>-2</sup>) has been recently achieved for sDSCs. This impressive photovoltaic performance was attributed to the high hole conductivity of PEDOT (2.0 Scm<sup>-1</sup>) generated from PEP, as well as the effective dye blocking effect, leading to a high yield of charge collection.

Zinc oxide (ZnO) has been reported as an alternative for dye-sensitized solar cells (DSSCs) due to it offers a large direct band gap of 3.37 eV, which is similar to TiO<sub>2</sub> and high electron mobility as well as provide surface area for dye-loading. Furthermore, ZnO also can be tailored to various nanostructures as compared to TiO<sub>2</sub> that provides a promising means for improving the performance of the photoanode in DSSCs.

In this study, we synthesize ZnO crystals with structures of hexagonal club (HC), intergrowth nanoparticles (INP), and hexagonal plate (HP) by microemulsion technique using the surfactants of cationic cetyltrimethylammonium bromide (CTAB), nonionic Triton<sup>®</sup> X-100, and anionic docusate sodium (AOT), respectively. From the X-ray diffraction (XRD) analysis, all the synthesized ZnO crystals show obvious peaks corresponding to (100), (002), (101) planes of ZnO, namely the wurtzite crystal phase. The scanning electron microscopy (SEM) and high-resolution transmission electron microscopy (HR-TEM) images (Fig. 1) reveal that each HC ZnO has two opposite hexagonal faces (parts), and it has average diameter of 350 nm and average length of 500 nm for each part; the INP ZnO has average diameter of 20~50 nm and inter-grown with each particle; the HP ZnO has average width of 650 nm and thickness of 120 nm. We believe that both the sub-micro sized HC and HP ZnO crystals will be meritorious in the present work as large particles are effective for light scattering; the nano-sized INP ZnO crystal will be meritorious in the present work as intergrowth structures are effective for electron transport in the photoanode of DSSCs. As expected, we obtained higher cell efficiency of 7.72% by using INP/HC/HP composite photoanode, as compared with commercial ZnO nanoparticles (3.53%).

\*E-mail: kcho@ntu.edu.tw

Recently, dye-sensitized solar cells have attracted more and more attention because the advantages of their high conversion efficiencies, low costs and simple preparation processes. In addition, they can work under low-light intensity and be applied onto flexible substrates. However, the development of DSSCs is limited by the usage of the expensive Pt counter electrode. Thus, the aim nowadays for developing a substitute material is not only to reach high cell efficiency ( $\eta$ ) but to maintain a low cost. Among all the potential substitutes, researchers have paid an intensive attention to cobalt selenide due to its earth abundance, high conductivity, and good electro-catalytic ability. Cobalt selenide counter electrode (CE) often possesses a structure of bulk or particles, thus the lack of dimensional electron transfer pathways and low active surface areas confine the pertinent DSSCs' performance.

In this work, we aim to prepare a low dimensional CoSe<sub>2</sub> with a structure of hierarchical nano-wall via a simple electro-deposition process. First, the cleaned fluorine-doped tin oxide glasses (1 cm<sup>2</sup>) were separately used as the working electrodes for a three-electrode system in three different aqueous bathes containing 5.0 mM cobalt chloride and 0.75 mM selenourea with pH values of 4.0, 6.0, and 8.0; the obtained CoSe<sub>2</sub> films were denoted as CoSe<sub>2</sub>-4, CoSe<sub>2</sub>-6, and CoSe<sub>2</sub>-8, respectively. A Pt foil and a Ag/Ag<sup>+</sup> electrode were used as the counter and reference electrodes, respectively. A pulse-potential voltage procedure was applied for 100 cycles for each bath; one cycle contained -0.9 V for 6 s and 0 V for 4 s. The obtained CoSe<sub>2</sub> films were treated via a post annealing process at 500 °C for 30 min in vacuum to obtain a good crystallinity. From the field-emission scanning electron microscopy (FE-SEM) images shown in Fig. 1, the CoSe<sub>2</sub>-4, CoSe<sub>2</sub>-6, and CoSe<sub>2</sub>-8 show the lump-like, ball-like and hierarchical nano-walled-like surface morphologies, respectively. Among them, CoSe<sub>2</sub>-8 simultaneously possesses the two-dimensional (2D) structures and a porous surfaces, which imply an outstanding electron transfer capability and a great electro-catalytic ability, respectively. From the cyclic voltammetry (CV) analysis, the cathodic peak current densities of CoSe<sub>2</sub>-4, CoSe<sub>2</sub>-6, and CoSe<sub>2</sub>-8 are 1.49, 1.36, 1.70 mA cm<sup>-2</sup>, respectively; indicating the electro-catalytic ability of those CoSe<sub>2</sub> films shows a tendency of CoSe<sub>2</sub>-8 > CoSe<sub>2</sub>-6 > CoSe<sub>2</sub>-4. In Fig. 1(e), the DSSCs with CoSe<sub>2</sub>-4, CoSe<sub>2</sub>-6, and CoSe<sub>2</sub>-8 CEs give the  $\eta$ 's of 8.41%, 7.83%, and 8.92%, respectively. It is notable that the hierarchical nano-wall CoSe<sub>2</sub>-8 renders the best  $\eta$ , which is even higher than that of Pt (8.25%); therefore, the earth abundant CoSe<sub>2</sub>-8 is a very promising material to replace Pt.

Fig. 1 FE-SEM images of (a) Pt film (b) CoSe<sub>2</sub>-4, (c) CoSe<sub>2</sub>-6, and (d) CoSe<sub>2</sub>-8. (e) Photocurrent density-voltage curves of the DSSCs with Pt and CoSe<sub>2</sub> CEs, obtained at 100 mW cm<sup>-2</sup>.

# Efficient Quasi-Solid-State Dye-Sensitized Solar Cells with Novel Polymeric Ionic Liquids

Polymeric ionic liquids (PILs) have stirred great interest in the fields of polymer chemistry and materials science, not only because of the combination of the unique properties of ILs with the macromolecular architecture, but also a matter of creating new properties and functions. The major advantages of using a PIL instead of a traditional IL are the enhanced mechanical stability, improved processability, durability, and spatial controllability over the traditional IL species. Recently, PILs have been demonstrated as promising quasi-solid-state (QSS) electrolytes in dye-sensitized solar cells (DSSCs) for improving the cell efficiency or durability.

In this study, we synthesized two kinds of polymeric ionic liquids, named as RAFT-A and RAFT-B (Fig. 1), for the use of quasi-solid-state electrolyte in DSSC. The QSS-DSSC with RAFT-A achieved 7.15% cell efficiency ( $\eta$ ) having open-circuit voltage ( $V_{OC}$ ) of 0.75 V, short-circuit current density ( $J_{SC}$ ) of 14.69 mA cm<sup>-2</sup>, and fill factor ( $FF$ ) of 0.65. Meanwhile, the QSS-DSSC with RAFT-B exhibited an  $\eta$  of 7.71%, with  $V_{OC}$  of 0.79 V,  $J_{SC}$  of 14.86 mA cm<sup>-2</sup>, and  $FF$  of 0.60. In order to realize the difference of the cell efficiencies, the electrochemical impedance spectroscopy (EIS) technique was employed to analyze the interfacial resistance in pertinent DSSCs. It was found that the charge-transfer resistance at the TiO<sub>2</sub>/dye/electrolyte interface ( $R_{CT}$ ) of the QSS-DSSC with RAFT-B is lower than that of the cell with RAFT-A. Moreover, from the Bode plot of the above EIS data, we found that the QSS-DSSC with RAFT-B shows longer electron life-time (8.69 ms) than the cell with RAFT-A (7.39 ms). These EIS results are in consistency with their photovoltaic performances. These properly designed PILs pave a promising way for developing highly efficient QSS-DSSCs.

Fig. 1: The chemical structures of RAFT-A and RAFT-B.

Fig. 2: Photovoltaic performance of the QSS-DSSCs with PILs, measured under 100 mW cm<sup>-2</sup>

# Thin film metallic glass as a diffusion barrier for flexible CIGS solar cell on stainless steel substrate: A feasibility study

Lingjun Xue, Jinn P. Chu\*, [Wahyu Diyatmika](#)

*Department of Materials Science and Engineering, National Taiwan University of Science and Technology*

*No. 43, Sec. 4, Keelung Rd., Da'an Dist., Taipei 10607, Taiwan (R.O.C.)*

*\*e-mail address: [jpchu@mail.ntust.edu.tw](mailto:jpchu@mail.ntust.edu.tw)*

Due to its high efficiency, long-term stable performance and potential for low-cost production, Copper indium gallium selenide (CIGS) solar cells have attracted considerable interests for the last decades. One of the trends is to fabricate them on flexible stainless steel substrates. However, during the high temperature processes, the detrimental elements from the substrates (mainly iron) may diffuse into the absorber layers, causing serious degradation in efficiency. In this study, we examine the feasibility of applying thin film metallic glasses (TFMGs) as diffusion barriers. In our preliminary works, the multilayer structures of steel/TFMG/Mo and steel/Mo were annealed and investigated. X-Ray diffraction results showed clear evidence of diffusion of Fe in the absence of TFMG barrier. According to this promising result, the CIGS solar cell devices were then processed and studied. The TEM-EDS results indicated that TFMG barrier efficiently blocked the substrate elements. The current-voltage (I/V) curve measurements results showed improved efficiency by depositing TFMG barrier. Between the two barriers, Zr-based TFMG barrier had better performance.

**Keywords:** CIGS thin film solar cell, stainless steel, thin film metallic glass, diffusion barrier

# A Novel Preparation Method for Titanium Dioxide in the Rutile Phase for Electrochemical Photocatalytic Applications

Solar water splitting on semiconductors (*e.g.*,  $\text{TiO}_2$ ) has been proposed to be a potential process for hydrogen generation. Since the bandgap of n-type  $\text{TiO}_2$  in the anatase phase is known to be 3.2 eV, it is a challenge for effective separation of electron/hole pairs under the visible light irradiation. This work aims to develop a  $\text{TiO}_2$  photo-anode with a high photocurrent density under the solar light illumination although most studies focused on the solar performance under the ultra violet (UV) light. This study tries to modify the Ti foil, including thermal growth of  $\text{TiO}_2$  in the rutile phase (R- $\text{TiO}_2$ ) and warm-water growth of R- $\text{TiO}_2$  nanoparticles with calcinations. These  $\text{TiO}_2$ -coated Ti photo-anodes possess outstanding photocatalytic abilities, which are considered to be promising electrochemical photocatalysts for solar energy applications. For example, R- $\text{TiO}_2$  with different compositions was successfully formed on titanium foils via thermal sintering between 300 and 900°C. This material is used as the photo-anode under simulated solar (visible) light illumination for water splitting and methylene blue degradation. The  $\text{TiO}_2$  photocurrent density performance is shown in **Fig. 1**. The photocurrent density of this photo-anode reaching  $337 \mu\text{A cm}^{-2}$  is obtained at an applied voltage of 3 V, which shows excellent stability over 1 V. Moreover, scanning electron spectroscopy (SEM), X-ray diffraction (XRD), UV-Vis diffuse reflectance spectra (DRS) are employed to characterize the films. The data of photocurrent-electrode potential curves, open-circuit potential, and cyclic voltammetry were employed to substantiate the explanations.

**Fig. 1** The photocurrent density against potential (*i-E*) curves for an R- $\text{TiO}_2$ /Ti photo-anode in 0.5 M  $\text{Na}_2\text{SO}_4$  under the simulated sunlight irradiation.

# Infrared transparent $\text{NiCo}_2\text{O}_4$ thin film as a Front Electrode for Solar Cells

Shu-Yi Tsai<sup>1</sup>, Chung-Ta Ni<sup>1</sup>, Kuan-Zong Fung<sup>1</sup>

<sup>1</sup>Research Center for Energy Technology and Strategy, Department of Materials Science and Engineering, National Cheng Kung University, No. 1, University Road, Tainan 70101, Taiwan, ROC  
willxkimo@yahoo.com.tw

Although most n-type TCOs have been used for applications such as passive components including transparent electrodes and IR reflecting coatings etc. TCOs with unique infrared transparency and adequate electrical conductivity are very useful in certain important applications. TCO like  $\text{NiCo}_2\text{O}_4$  is generally regarded as a mixed valence oxide that adopts an inverse spinel structure in which nickel occupies the octahedral sites and cobalt is distributed over both octahedral and tetrahedral sites<sup>1-3</sup>. Recently,  $\text{NiCo}_2\text{O}_4$  spinel thin film was found to be an infrared transparent conducting material with potential for optoelectronic applications. However, nickel-cobalt oxide spinel tends to become  $(\text{Ni},\text{Co})\text{O}$  with rock salt structure at higher temperatures. Thus, the functional properties of nickel-cobalt oxide are highly dependent upon its processing conditions such as precursors, temperatures, annealing atmospheres.

In this study, nickel-cobalt oxide with spinel structure was obtained from nitrates precursors after calcinations at 300°C for 24 h. With the proper selection of the annealing temperature,  $\text{NiO}$  and  $\text{CoO}$  may form conducting spinel structure or nearly perfect solid solution with rock salt structure. The sputtering deposited  $\text{Ni-Co-O}$  films also showed more than 70% transmittance in the infrared range. The electrical property of spinel film is measured using 4-probe technique. A resistivity as low as  $10^{-2} \sim 10^{-1}$  ohm/cm is obtained. The optical property of this spinel is also measured as a function of thickness/deposition time in the infrared wavelength range.

Fig. 1. XRD patterns of  $\text{Ni-Co}$  Oxide heated at various temperatures at 300°C, 500°C, 1000°C, 1500°C (from bottom to top)

Fig. 2. Resistivity of  $\text{Ni-Co}$  Oxide plotted as a function of calcination temperatures at 300°C, 500 °C, 1000°C, and 1500°C.

## Abstract:

Oih-PSCs have rapidly grown to the vanguard of solution-processable photovoltaic devices, however, the  $\text{CH}_3\text{NH}_3\text{PbI}_3$  light harvesting material degrades rapidly in ambient air, hindering their practical applications. In this work, we report a systematic investigation of laser induced degradation of Oih-perovskite. By using Raman spectroscopy and Photoluminescence spectroscopy to monitor structure and phase transformation in Oih-perovskite degradation process, we show the formation of a lead iodide,  $\text{PbI}_2$ , as the final step of the degradation mechanism and degradation product.

Development of advanced types of solar cells has tremendously accelerated in recent years all activities in the photovoltaics (PVs) driven by the needs to produce solar panels with as high efficiency as possible at lowest cost possible [1]. Realizing that classical silicon solar cells have their limits, such as poor function at low light intensities, lots of research has been carried out past two decades towards alternative technologies based on thin film solar cells (amorphous Si-H, CIGS, CdTe) [2], perovskite cells [3], dye-sensitized cells [4], and organic cells [5]. Even though, the overall efficiencies of advanced photovoltaic devices have grown up significantly (and this goes hand in hand with the development of production technologies), there is so far no solar cell that would have reliable stability and performance over many years of the cell service, that would be cheap, environmentally reasonable and potentially flexible. One of most competing technologies to silicon solar cells, when considering the efficiency, low-cost production and stability is based on thin films of semiconducting chalcogenides, such as Cu(In,Ga)Se<sub>2</sub> (CIGS) [6,7]. CIGS became recently materials of the choice as they represent in thin film solar cells chromophores of adjustable band gaps, good radiation stability and high optical absorption coefficient.

For solution processed CIGS thin film PVs cells, however, the limiting factors for further enhancement of the conversion efficiency involve the shape, size and grain boundaries of the chromophore films. The film morphology, defects and character of the grain boundaries predetermine the mobility (the loss) of free carriers in the chromophore film resulting in conversion efficiency maximum ~10 % for CIGS materials and multilayer solar cell design [8].

It is the grain size that is believed as crucial factor limiting the efficiency of photon-to-current conversion in current CIGS-based photovoltaic cells, especially solution processed [8]. It is very clear that in case of micrometer-thick chromophore layers in current multilayer cell design, the morphology of the chromophore layer is a function of deposition conditions and post-annealing treatment. Therefore, the variation of the grain size is limited resulting in lower efficiencies than are theoretically possible [8].

Among several more or less feasible approaches, there seems to be one straight-forward solution to improve the carrier mobility of semiconducting chalcogenides to the highest possible level with the projection to significantly increase the solar-to-electricity conversion efficiency of the CIGS solar cell. It stems from the use of high aspect ratio semiconducting TiO<sub>2</sub> nanotube arrays [9].

The presentation will show initial photo-electrochemical results for anodic TiO<sub>2</sub> nanotubes employed as highly ordered electron-conductive supports for host materials - chromophores with a suitable light absorbing capabilities, stability and great anchorage to TiO<sub>2</sub> nanotubes. We will focus on chromophores based on inorganic chalcogenides [10] and organic push-pull molecules [11].

# Performance Enhancement of Perovskite-based Solar Cells with TiO<sub>2</sub> Scaffold by Optimizing Electron-Hole Transport

Hye-Rin Kim, Moon-Sung Kang

*Department of Environmental Engineering, Sangmyung University  
300 Anseo-dong, Dongnam-gu, Cheonan-si, Chungnam 330-720, Republic of Korea  
solar@smu.ac.kr*

In recent years there has been increased attention to perovskite solar cells due to their attractive features such as high energy conversion efficiency and low energy production cost. Due to its ambipolar and high light absorbing properties, perovskite can be used as efficient light absorber as well as electron (e<sup>-</sup>) or hole (h<sup>+</sup>) transport materials. During the past several years, the energy conversion efficiencies of the perovskite solar cells have been dramatically increased. The enhancement in the perovskite solar cell performances is mostly attributed to the development of efficient perovskite materials and structural configuration. However, many aspects of the photovoltaic properties are needed to investigate for further improvement of the solar cell efficiency. In this work, we have systematically studied the effects of photoelectrode and hole transport material (HTM) additives (*e.g.* *t*-BP and Li salt) on the photovoltaic characteristics. The perovskite solar cells were prepared by using conventional organometal halides (*e.g.* CH<sub>3</sub>NH<sub>3</sub>PbI<sub>3</sub>) and HTMs (*e.g.* Spiro-MeOTAD) as the base materials. A uniform and pinhole-free hole-blocking layer is necessary for high-performance perovskite-based solar cells. Several metal oxides were investigated to form thin blocking layers. We utilized the spin coating or screen printing method to coat the thin metal oxide layer on transparent conductive oxide substrate. Highly ordered nanoporous TiO<sub>2</sub> scaffold layer was also prepared via a surfactant-templating method for efficient charge transport. The effects of various additives on the photovoltaic properties were studied in terms of the electron-hole transports. The charge transport characteristics in the photoelectrode were systematically investigated through IMVS/IMPS and SLIM-PCV measurements.

Since the petrochemical energy resource causes the serious environment pollution, the development of the renewable energies becomes urgent and important. Dye-sensitized solar cells converting solar energy into electricity have attracted extensive attention since it was reported by Grätzel in 1991. A typical DSSC contains photoanode, counter electrode (CE), and  $\text{I}^-/\text{I}_3^-$  based redox electrolyte. However, noble platinum (Pt) is usually used as a CE material in DSSCs, thus resulting in the increase in the manufacturing cost of DSSCs.

Up to now, several low-cost alternatives have demonstrated Pt-like properties as CEs, such as carbon-based materials, conducting polymers and inorganic compounds. Among them, metal sulfides including CoS, NiS,  $\text{MoS}_2$  and  $\text{WS}_2$  have been considered as potential alternatives due to their excellent electrocatalytic activity. In this study,  $\text{NiCo}_2\text{S}_4$  (NCS) CE was prepared using a facile dip-coating method. First, NCS particles were synthesized via a hydrothermal method, and then dispersed in aqueous solution. Afterwards, bare fluorine-doped tin oxide (FTO) glass substrates were dipped in the surface-conditioner solution for 1 min, and subsequently dipped in the as-prepared NSC suspension solution for 10 min. It should be noted that the dip-coating approach has lots advantages including low cost, simply, without complicated equipment, and suitable for mass production. The DSSC assembled with the as-fabricated NCS CE exhibited a superior photovoltaic conversion efficiency of up to 6.95% than that of the device with Pt CE (6.36%), signifying its promising potential as a low-cost Pt-free CE in DSSCs.

# Surface Textured Silicon Photocathode for H<sub>2</sub> Production improves Photoelectrochemical Water Splitting efficiency

The generation of hydrogen by solar-driven water-splitting is the focus of much current research, because it has the potential to be a clean and sustainable abundant energy source. Silicon is the most widely used semiconductor material in photovoltaic devices, due to its relatively low-cost and small band gap. Silicon surfaces with extremely high roughnesses not only exhibit enhanced light-trapping effects but also have a lower overpotential for photoelectrochemical hydrogen half-reactions. These qualities have resulted in photovoltaic device improvements with respect to optical, electrical, and chemical activity. A lot of methods, focused on silicon surface texturing, have been reported in the literature, e.g. surface etching. In this study silicon wafers with specific crystal planes were etched to form pyramid structures by using alkaline etching techniques. We combined alkaline etching and metal-assisted chemical etching to fabricate structures that included pyramids supporting nanowires. Both Si pyramids and nanowires were shown to significantly decrease light reflection. Based on this dual structure, light absorption, surface reaction areas and the resulting overall efficiency of photoelectrochemical H<sub>2</sub> production can be improved when compared to untreated silicon.

# **The Study of Carrier Transport/Transfer Mechanism inside CZTS/MS(M=Zn, Cd, Cu)/TiO<sub>2</sub> Nanorods for Solar Water Splitting**

Tsung-Yeh Ho, Liang-Yih Chen\*

*Department of Chemical Engineering, National Taiwan University of Science and Technology  
43, Section 4, Keelung Road, Taipei, 106, Taiwan.*

*sampras@mail.ntust.edu.tw*

Copper zinc tin sulfide (Cu<sub>2</sub>ZnSnS<sub>4</sub>, CZTS) is a kind of light-harvesting candidate material for solar energy conversion through photovoltaics or photoelectrochemical, owing to its suitable band gap (~1.5eV), non-toxic and high absorption coefficient (~10<sup>4</sup> cm<sup>-1</sup>). In this study, CZTS nanocrystals were coated on TiO<sub>2</sub> nanorods (NRs) with different kinds of chalcogenides as buffer layer, such as zinc sulfide (ZnS), cadmium sulfide (CdS) and copper sulfide (CuS). According to band alignment analysis, this a suitable heterogeneous structure could efficiently separate photogenerated electrons and holes. From performance analysis we found that the conversion efficiency of photoelectrode with CuS buffer layer could achieve 2.25% at 0.5V vs. RHE under illumination of one sun AM 1.5G. In the stability test, the CZTS/CuS/TiO<sub>2</sub> NRs could maintain 30 min without seriously decay at 1.23 V vs. RHE. UV-visible spectroscopy and Cyclic voltammetry (CV) were used for ~~the-determining~~ the bandgap and band edge positions of CZTS under different synthesis conditions. Finally, the carrier transport/transfer mechanism inside CZTS/MS (M=Zn, Cd, Cu)/TiO<sub>2</sub> NRs was characterized by electrochemical impedance spectroscopy (EIS) under one sun AM 1.5 G.

# Fabrication of Ti doping Hematite Nanotubes Arrays Photoanode via Anodic Electrodeposition for Solar Water Splitting

Yen-Jhih Chen and Liang-Yih Chen\*

*Dep. of Chemical Engineering, National Taiwan University of Science and Technology*

*No.43, Sec. 4, Keelung Rd., Da'an Dist., Taipei 106, Taiwan*

*sampras@mail.ntust.edu.tw*

Due to the suitable band gap ( $E_g = 2.1$  eV), hematite ( $\alpha\text{-Fe}_2\text{O}_3$ ) can allow light to be absorbed in visible region. Besides In addition, hematite is nontoxic and stable in water, so it is a suitable semiconductor material for solar water splitting. Herein, an anodic electrodeposition was developed to fabricate hematite nanotubes for harvesting the light and increasing the light scattering. In the syntheses, ZnO nanorods (NRs) prepared by hydrothermal method were immersed in  $\text{FeCl}_2$  aqueous solution as work electrode and were biased at 1 V vs. Ag/AgCl. During the process, ZnO NRs were reduced as  $\text{Zn}^{2+}$  ions to dissolve in aqueous solution and  $\text{Fe}^{2+}$  ions were oxidized as  $\text{Fe}^{3+}$  ions to form  $\gamma\text{-FeOOH}$  shell layers on the surfaces of ZnO NRs. Until all ZnO NRs were dissolved completely in aqueous solution,  $\gamma\text{-FeOOH}$  nanotubes were formed. To transform  $\gamma\text{-FeOOH}$  nanotubes as  $\alpha\text{-Fe}_2\text{O}_3$  nanotubes, a post-annealing process was employed at  $500^\circ\text{C}$ . However, the poor conductivity and slow oxygen evolution kinetic rate limited the performance of hematite photoanodes solar water splitting system. In order to enhance the conductivity, doping Ti ions into hematite nanotubes and promoting the crystalline at  $650^\circ\text{C}$  annealing temperature were conducted. Ti doping hematite nanotubes photoanode was decorated by  $\text{ZnFe}_2\text{O}_4$  layer and Co-Pi oxygen evolution catalysts furthermore to increase the band bending and to improve the carrier transfer rate in the interfaces of photoanode and electrolyte for optimizing water oxidation.

# Rutile TiO<sub>2</sub> Nanosheet Arrays on Thermally Oxidized TiO<sub>2</sub> Blocking Layer for Enhancing Efficiency of Perovskite Solar Cells

Nan Zhang, Miaoqiang Lv, Meidan Ye, Dajiang Zheng, Changjian Lin\*

*E-mail: [cjlin@xmu.edu.cn](mailto:cjlin@xmu.edu.cn)*

**ABSTRACT:** Here we report a highly efficient perovskite solar cell based on a thermal oxidation TiO<sub>2</sub> compact layer and mesoporous TiO<sub>2</sub> nanosheet arrays(NSAs). The highly oriented two-dimensional(2-D) single-crystalline rutile TiO<sub>2</sub> were grown hydrothermally on the sputtered Ti film following one-step sintering process. This two-dimensional TiO<sub>2</sub> nanomaterial has advantages of enhancing charge collection and efficient incorporation of perovskite particles. Through the facial one-step sintering process, we have obtained a perovskite solar cell with photocurrent density of 21.03 mA/cm<sup>2</sup>, voltage of 0.90V, filling factor of 62.26% and power conversion efficiency (PCE) of 11.82% under the simulated AM 1.5G one sun illumination.

# Electrochemical Analysis of Dye Sensitized Solar Cell Employing Indoline-based and Ruthenium-based Dye Combined with Volatile and Non-Volatile Solution-based Electrolyte

Gerald Ensang Timuda, Runbang Tao, Keiko Waki

Dye Sensitized Solar Cell (DSSC) was prepared using different combination of dyes and electrolytes. The dyes used are Ruthenium based, N719 dye, and Indoline-based, D205 dye. Both of the dyes was used in combination with electrolytes using volatile Acetonitrile based solvent and non-volatile 3-Methoxypropionitrile based solvent namely AN-50 and Z-50, respectively.

Under AM 1.5 simulated light source, the solar cells using AN-50 electrolyte show better performance than the Z-50. The N719 and D205 dyes show similar comparison of performance when they combined with AN-50 electrolyte, which shows the potential of this Indoline-type dye in competing with the well-known Ru-based, N719 dye. Interestingly, the D205 dye show apparent better performance than the N719 when Z-50 is used as electrolyte. Electrochemical Impedance Spectroscopy (EIS) at open circuit condition under AM 1.5 illumination was carried out to study intrinsic properties of the solar cells that responsible for the performance obtained. It was found that in this study, the electron diffusion length,  $L_n$ , of the solar cells employing AN-50 as the electrolyte is longer than the thickness of the  $\text{TiO}_2$  photo-anode film, which is the requirement of the efficient solar cell. Employing the same Z-50 electrolyte, the cell using D205 dye have  $L_n$  shorter than the  $\text{TiO}_2$  thickness, but still longer than the one using N719 dye, which explaining bigger performance obtained.

To scrutinize the mechanism involved in the power generation and study the effect of the carrier concentration on the impedance parameters, EIS measurement was carried out under different light intensity. The result will be presented and further discussed.

e-mail gutkowski.ramona@rub.de

Searching for efficient semiconductor materials for light induced water splitting with low band gaps absorbing in the visible part of the solar spectrum is of high interest. It is anticipated that the search for suitable materials is more successful investigating ternary or quaternary semiconductors instead of single metal oxides such as TiO<sub>2</sub> or ZnO. BiVO<sub>4</sub> is a promising and well-studied n-type semiconductor with a band gap of around 2.4 eV. Nevertheless, BiVO<sub>4</sub> itself is a bad electron conductor with additionally low hole transfer kinetics resulting, independently of the preparation method, in high recombination rates of photogenerated electron-hole pairs, thus limiting the efficiency.

In our work we searched for a way to further improve the photoelectrocatalytic efficiency of anodic deposited BiVO<sub>4</sub> films on FTO. Doping with different metals is a well-known method to increase the incident photon-to-current efficiency (IPCE), but strongly depends on the preparation method. For example, single doping with molybdenum<sup>1</sup> led to an increase of the IPCE for spin-coated films obtained by the metal-organic-decomposition method, while inject-printed BiVO<sub>4</sub> doped with molybdenum showed no increase in the IPCE. Furthermore, just by doping with tungsten a significant increase of the IPCE was observed<sup>2</sup>. Doping of BiVO<sub>4</sub> with Mo/W using a dispensing robotic system increased the IPCE up to 12 % at wavelengths below 400 nm<sup>3</sup>.

We employed anodic deposition of BiVO<sub>4</sub> and added different metal salts to the precursor solution. For doping with Fe, Mo and W we observed 10 times higher IPCE values (up to 20 % at 480 nm) as compared with the un-doped BiVO<sub>4</sub>. A further increase of the IPCE was achieved by doping BiVO<sub>4</sub> with W/B, W/Zn and especially with Mo/Zn and Mo/B, assuming improved electron conductivity leading to lower recombination of photogenerated electron-hole pairs finally resulting in higher photoelectrocatalytic efficiency.

A second method to improve the photoelectrocatalytic performance is the decoration of BiVO<sub>4</sub> or metal doped BiVO<sub>4</sub> with co-catalysts. Commonly Co-Pi<sup>2,4</sup>, FeOOH<sup>5</sup>, Co-borate<sup>6</sup>, Ni-borate<sup>7</sup> were used as co-catalysts for increasing the photocurrent of BiVO<sub>4</sub> modified electrodes. We focused on electrochemical deposition of Ni-based co-catalysts, like Ni-Co-oxide or Ni-Fe-oxide compared to Ni-oxide, Co-oxide and Fe-oxide. The layer thickness of the co-catalyst plays an important role and is proportional to the deposition time. A high co-catalyst loading blocks the incident light and consequently less photocurrents are observed. Beside the deposition time and concentration of the co-catalyst precursor the deposition technique, e.g. photodeposition, electrodeposition and photo-assisted electrodeposition are key parameters for the decoration of BiVO<sub>4</sub> with co-catalysts to enhance the oxygen evolution reaction. To have a fast deposition and characterization of these different co-catalysts a specifically designed optical scanning droplet cell with an automated electrolyte exchanging system was used. In this way we were able to create co-catalyst libraries and to directly characterize those avoiding time consuming conventional electrode preparation and deposition. Hence, we were able to compare photocurrents of different co-catalyst loadings, deposition techniques and deposition times on Mo-doped BiVO<sub>4</sub> in dependence on the applied bias potential.

# Bi<sub>2</sub>S<sub>3</sub> Nanoparticle Modified TiO<sub>2</sub> Nanotube Arrays for High Efficiency of Photoelectrochemical Hydrogen Production

Zhi Wu, Yufeng Su, Jiangdong Yu, Lan Sun, Changjian Lin

State Key Laboratory for Physical Chemistry of Solid Surfaces, Department of Chemistry, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen 361005, China

H<sub>2</sub> generation from photoelectrocatalytic water splitting utilizing solar light has attracted much interest ever since Fujishima and Honda firstly reported in 1972.<sup>1</sup> However, photoelectrochemical methods of conversion of solar energy to electrical or chemical power have suffered from low efficiency.<sup>2</sup> A way to enhance the photoactivity is to construct heterosystems which consist of a wide band gap n-type semiconductor combined with a narrow band gap semiconductor. Bismuth sulfide Bi<sub>2</sub>S<sub>3</sub> seems to be an appropriate material with a direct band gap of 1.28 eV and captures a large part of the solar spectrum, which is close to the ideal value required for photoelectrochemical applications.<sup>3-4</sup> In this work, the Bi<sub>2</sub>S<sub>3</sub> nanoparticles modified TiO<sub>2</sub> nanotube arrays (Bi<sub>2</sub>S<sub>3</sub>@TNTAs) were constructed by sequential chemical bath deposition (CBD) method. This unique heterostructure exhibited improved photoelectrochemical activity as compared to pure TiO<sub>2</sub> TNTAs. When adopted as photoanode, a more than 12-fold enhancement in photocurrent response was achieved, especially, the maximum hydrogen production rate reached 657  $\mu\text{mol}/(\text{h}\cdot\text{cm}^2)$  under 0.5 bias potential.

Titanium metal possesses high strength-to-weight ratio and excellent corrosion resistance. Due to these properties, titanium and its alloys find applications as structural materials in the aerospace and defense industry. However, titanium extraction from its ore via the conventional, non-electrolytic Kroll process is complex, energy-intensive and thus costly. Electrolytic extraction has been attempted previously albeit without success. A critical hurdle in electrolytic titanium extraction is the presence of multivalent titanium ions in the electrolytic cell, which trigger undesired processes of redox-shuttling and bipolar reactions. These processes destabilize the cell operation and drastically lower the cell efficiency.

At Case Western Reserve University, we are developing a revolutionary electrolytic titanium extraction process that addresses the aforementioned technical hurdles. Our process is based on the electrolysis of titanium tetrachloride from high-temperature (400-500°C) molten salts. The key innovation in our electrowinning process is a specialized diaphragm stack, which separates the catholyte and anolyte compartments of the cell. The diaphragm stack is designed to eliminate extraneous bipolar reactions while retarding the redox shuttling of multivalent titanium ions in the cell. This enables stable and energy-efficient electrolytic extraction of titanium sponge. In this talk, we will outline the fundamental electrochemical principles governing the operation of our electrolytic cell. The construction and operation of a prototype electrowinning reactor, and reactor performance in terms of the electrowinning efficiency and titanium sponge purity, will be discussed. Broader impacts of our electrowinning approach to other multivalent metal systems will be outlined.

# SLRR of UPD Monolayers – Fundamental Aspects and Interplay of UPD, Reaction Kinetics, and Nucleation

Stanko R. Brankovic<sup>1</sup>, Ela Bulut<sup>1</sup>, Dongjun Wu<sup>1</sup>, Hasan Kilic<sup>2</sup>,

<sup>1</sup>ECE Department, University of Houston, Houston, Texas, 77204-4005, USA

<sup>2</sup>Marmara University, Istanbul, Turkey

SRBrankovic@uh.edu

The deposition protocol based on *Surface Limited Redox Replacement* (SLRR) reaction of UPD monolayers [1] has gained a lot of attention in recent years [2-9]. The monolayers as well as thin films of arbitrary thickness can be deposited with great fidelity using this approach [9,10]. Their nucleation and morphology is found to be a direct function reaction kinetics of SLRR [11]. Understanding of the interplay between the experimental conditions during SLRR on one side and resulting SLRR reaction kinetics on the other is necessary if the true control of the deposit morphology is to be assumed using this deposition protocol.

Our work explores a fundamental relation between kinetics of Au deposition via SLRR of Pb UPD ML and experimental parameters of the SLRR process such as concentration of the UPD metal and depositing metal ions in the solution, effect of complexing agents and ions such as citrate, effect of temperature and effect of supporting electrolyte. The reaction solution in our kinetics studies contained both  $Pb^{2+}$  and  $Au^{3+}$  ions in 0.1 M  $HClO_4$  as a supporting electrolyte. The Pb coverage as a function of time during SLRR is calculated from the temporal change of the surface reflectivity. The typical results for Pb UPD ML coverage change during Au deposition via SLRR of Pb UPD ML obtained from reflectivity data are shown in Figure 1. Data such as one in Figure 1 are fitted with the model-rate equation of first order in terms of Pb UPD coverage which also takes into account the contribution of parallel SLRR of Pb UPD due to oxygen reduction reaction (ORR). This allowed a more realistic and more reproducible values of the rate constant,  $k'$ , for Au deposition process to be obtained. Our results

suggest a linear relation between the rate constant  $k'$  and  $Au^{3+}$  concentration. The increase in  $Pb^{2+}$  ion concentration for one order of magnitude increases the value of the fundamental rate constant for Au deposition via SLRR of Pb UPD ML for almost 100%. The presence of citrate ions in the solution lowers the value of rate constant but not significantly. The presented data show that effective manipulation of deposition kinetics can be achieved by proper choice of UPD and depositing metal ions concentration. This should have a strong implication when deposit morphology control is considered.

The authors acknowledge the support from NSF Chemistry division under the contract # 0955922.

Supported nanostructured electroactive materials are known to boost the efficiency of electrocatalytic processes. Although they can be fabricated by multiple methods, electrodeposition offers several advantages, since the nanostructures are grown on the final support. However, to produce highly electroactive nanostructures in a reproducible way, it is mandatory to optimize the electrodeposition processes. This requires a full understanding of the electrochemical nucleation and growth mechanisms on the nanoscale. During the last years, we have developed an approach based on using carbon coated TEM grids as electrodes. This way, by combining atomic-scale TEM characterization with electron tomography and electrochemical measurements, we have found evidence that has led us to suggest an electrochemical aggregative growth mechanism [1]. It includes nanocluster self-limiting growth, surface diffusion, aggregation and coalescence as important electrochemical growth mechanisms [2].

Besides, Deep Eutectic Solvents (DESs) have generated enthusiasm as a new generation of non-aqueous electrolytes [3]. Nanoscale electrodeposition from DESs is relatively new but has already been proven effective to deposit metallic nanostructures. Moreover, DESs are especially interesting because of their ability to stabilize nanoclusters [4] and to facilitate nanoparticle self-assembly. Hence, nanostructures that cannot be deposited from aqueous electrolytes could potentially be generated.

In this presentation, we first present a summary of the latest findings on the electrochemical nucleation and growth mechanisms involved in the generation of electroactive nanostructures, with special focus on phenomena such as nanocluster self-limiting growth and aggregation. Second, we discuss their electrocatalytic properties and stability. In this case, the evaluation of their structural and morphological features in 3D by electron tomography provides new insights into the processes leading to catalyst degradation [5]. Finally, we present the most recent findings on the electrodeposition of electroactive nanostructures from DESs. TEM characterization linked with electrochemical characterization allows studying the specific interactions of the solvent with the growing metallic phase [6]. These processes are of great interest to highlight possible benefits of the use of DESs as alternative electrolytes for nanoscale electrodeposition.

# The Synthesis and Characterisation of Mesoporous Silica Films for use in Supercritical Fluid Electrodeposition

Andrew Lodge, Calum Robertson, Andrew Hector  
Department of Chemistry, University of Southampton  
University Road, Highfield, Southampton SO17 1BJ, United Kingdom  
a1c10@soton.ac.uk

Supercritical fluids have several unique properties that make them potential solvents for use in electrodeposition. The most important of these properties is the negligible surface tension of supercritical fluids, which enables them to penetrate fully to the bottom of pores. Supercritical fluids are also able to dissolve electrolyte salts. These properties allow supercritical fluids to be used as solvents in the supercritical fluid electrodeposition (SCFED) of metals such as copper or germanium. This has the potential to be used in applications such as microelectronics.

The formation of silica mesopores has been undertaken using the Electrochemically Assisted Surfactant Assembly (EASA) method pioneered by Walcarius.<sup>[2]</sup> This system uses cationic surfactants such as cetyltrimethylammonium bromide to form a porous template, around which the silica is electrodeposited to form a film of vertically aligned mesopores with a constant diameter. These mesoporous structures have been successfully deposited on titanium nitride and indium-doped tin oxide substrates and have a pore diameter of approximately 1.6 nm.<sup>[3]</sup> The size of the pores has also been tuned through the use of additives such as mesitylene, giving a mesoporous film with an increased pore size of 2.4 nm. The pore size can also be further tuned by varying the cationic surfactant used for the EASA deposition. The surface chemistry of the pores can also be fine-tuned by the grafting of functional groups onto the surface of the pores.

The synthesis of mesoporous silica films by the EASA technique and their surface modification and characterisation will be shown. Also shown will be the results of initial SCFED results indicating that the growing of nanometre scale wires inside the pores is possible.

# The Spontaneous Potential Oscillations in a Galvanostatic Copper Electrodeposition

Po-Fan Chan and Wei-Ping Dow\*

*Department of Chemical Engineering, National Chung Hsing University  
No.250, Kuo-Kuang Road, South District, Taichung City 40227, Taiwan, R.O.C.*

\*[dowwp@dragon.nchu.edu.tw](mailto:dowwp@dragon.nchu.edu.tw)

The spontaneous potential oscillations are observed in a galvanostatic copper electrodeposition using specific organic additives. Electrochemical studies reveal that the appearance of the spontaneous potential oscillations during copper electrodeposition is strongly dependent on the electrode rotating speed and the current density. The potential only spontaneously oscillated in the range of  $-0.44\text{V} \sim -0.49\text{V}$  with respect to saturated mercury-mercurous sulfate electrode (SMSE). This result implies that the electrochemical reduction of copper ions at the metal/solution interface is affected by those organic additives, and the electrochemical oscillation reaction depends on a specific potential range, which may relate with the adsorbed chemical species. In addition, the waveform of the potential oscillation is adjustable by the electrode rotating speed and the current density, and it affects the crystal structure and the surface microstructure of the deposited copper. The plated copper layers were characterized by FIB, FE-SEM, and HR-TEM. The spontaneous potential oscillations observed in the copper deposition are explained according to the electrochemical studies and the corresponding microstructure analyses.

# **Electrodeposition of Zn-Mn-Mo layers from citrate solutions**

Honorata Kazimierzak, Agnieszka Hara, Piotr Ozga

*Polish Academy of Sciences, Institute of Metallurgy and Material Science,  
30-059 Krakow, 25 Reymonta st., Poland*

*h.kazimierzak@imim.pl*

Zinc-manganese-molybdenum layers are proposed as environmentally friendly material for corrosion protection of steel. The combination of zinc and manganese in the alloy exhibits a synergistic effect and can result in significantly higher corrosion resistance of Zn-Mn alloy than the resistance of zinc and manganese separately. Further increase of the corrosion resistance of such alloy layers may be obtained by the addition of a next component showing passivating properties. Hexavalent molybdenum have passivating properties, and further does not exhibit carcinogenic effect, associated with the use of hexavalent chromium. Hence, Zn-Mn-Mo can be considered as a substitute for zinc based layers with carcinogenic Cr(VI)-based conversion film.

The preparation of ternary Zn-Mn-Mo alloys is difficult by conventional thermal methods because there are great differences in the melting and boiling temperatures of alloys components. Also, the very limited solubility of molybdenum in zinc is a significant problem. Hence electrodeposition can be considered as a way to obtain such alloys, and moreover it is a relatively simple and low-cost method of producing coatings. Citrates form complexes with Zn(II), Mn(II) and Mo(VI) and are non toxic, furthermore they provide pH stabilisation of electrolyte solutions, hence citrate baths were proposed for the electrodeposition of Zn-Mn-Mo alloys

The main purpose of this work was to analyze the kinetics of co-reduction of zinc, manganese and molybdenum from citrate electrolytes and to study the complexes formation and their stability in Zn-Mn-Mo-citrate system. Next aim was to determine the optimal conditions for electrodeposition of Zn-Mn-Mo coatings.

The thermodynamic model was built to indicate the range of bath parameters in which were homogeneous and stable electroactive species of zinc, manganese and molybdenum. The electrodeposits were obtained from stable, homogeneous Zn(II)-Mn(II)-Mo(VI) citrate with different concentrations of metals and citrate ions. The electrodeposition of alloy was conducted on the rotating disc electrode in the potentiostatic conditions. The kinetics and mechanism of electrodeposition was studied by cyclic voltammetry and by the determination of partial polarization curves of metals deposition and hydrogen evolution, in selected solutions of electrolytes with various concentrations of the individual components and various pH. The surface composition was determined by chemical analysis (WDXRF). The morphology of the resulted coatings was studied by SEM technique.

# Room Temperature Electrodeposition of Elemental Magnesium and Aluminum from Glyme-Based Electrolytes

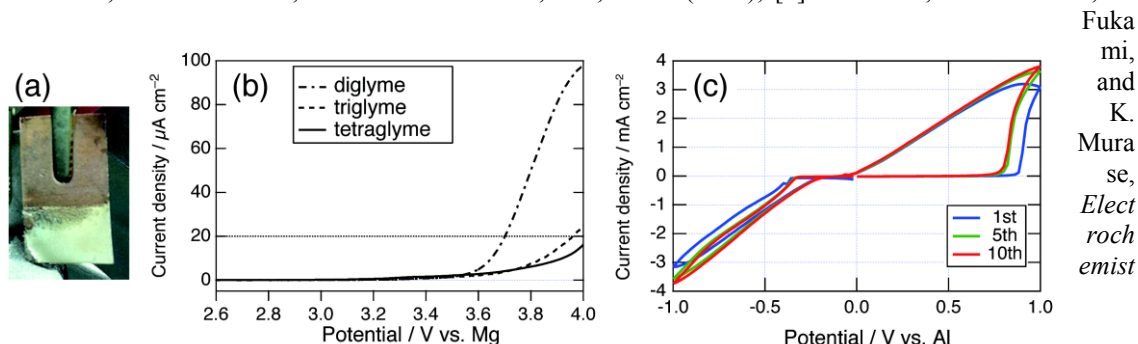

Atsushi Kitada, Yuu Kang, Kai Nakamura, Kazuhiro Fukami, Kuniaki Murase  
 Department of Materials Science and Engineering, Kyoto University  
 Yoshida-honmachi 36-1, Sakyo, Kyoto 606-8501, Japan  
 kitada.atsushi.3r@kyoto-u.ac.jp

Elemental magnesium (Mg) and aluminum (Al) have come to be viewed as interesting negative electrode materials for next generation secondary batteries because of their high energy densities (3839 mA h cm<sup>-3</sup> for Mg and 8042 mA h cm<sup>-3</sup> for Al), negative electrode potentials (−2.356 V vs. SHE for Mg and −1.68 V vs. SHE for Al) and natural abundance. Al is used for many industrial applications such as erosion-resistant plating. Because of their low electrode potentials aqueous solutions cannot be used, and thus efforts have been made to investigate aprotic solvents including ionic liquids (ILs) [1, 2]. However, problems including high volatilities even at room temperature (RT) and high moisture sensitivities of these reported electrolytes have prevented practical uses. Very recently Abe and Fukutsuka *et al.* reported that polyethyleneglycol dimethyl ethers (glymes) with boiling and flash points above 100 °C enable deposition and dissolution of Mg at RT [3]. Their approaches are quite reasonable to suppress volatilities with maintaining low cost. Our approach is based on (i) improvement of Mg electrolytes in terms of safety and (ii) investigation of novel electrolytes for Al electrodeposition using glymes. Here we introduce our recent studies on the several electrolyte solutions in which Mg or Al deposition and dissolution can take place at RT.

Elemental Mg was electrodeposited from a magnesium amide Mg(Tf<sub>2</sub>N)<sub>2</sub> and mixed solvents of glymes and an amide-based IL PP13-Tf<sub>2</sub>N [4]. Here PP13-Tf<sub>2</sub>N served as a supporting electrolyte, which increased conductivities from 0.50 to 2.6 mS cm<sup>-1</sup> at the Mg concentration of 0.1 mol dm<sup>-3</sup>, of which molar ratio was Mg(Tf<sub>2</sub>N)<sub>2</sub>:diglyme:PP13-Tf<sub>2</sub>N = 1:56:7. Flat deposition of Mg with metallic luster was successful on a Cu substrate at −1.0 V vs. Mg QRE using this solution (see Fig. 1a). It was also indicated that above −1.0 V dense deposition was difficult due to its large overpotential for Mg nucleation. Since the 1:56:7 mixed electrolyte was still volatile due to the presence of free or uncoordinated glyme molecules, we decreased the fraction of glymes to place more importance on safety of electrolytes. We prepared 1:8:7 mixtures, where almost all glymes coordinate to Mg<sup>2+</sup> and/or PP13<sup>+</sup> cations. In spite of the sizable decrease in glyme amount their conductivities were comparable (2.6–3.8 mS cm<sup>-1</sup>), and deposition and dissolution of Mg was observed as well. Moreover, their anodic stabilities became ca. +4 V vs. Mg as shown in Fig. 1b, much higher than the IL-free triglyme solution in ref. [3] (+3.4 V vs. Mg). Since anodic stabilities depend on degree of oxidative decomposition of glymes, the improvement should come from decrease in the amount of free glymes. However, sizable anodic overpotentials of about +0.6 V were observed for Mg dissolution [3,4]. How to reduce the anodic overpotentials is an open question in these amide-containing electrolytes.

Elemental Al was successfully deposited and dissolved at RT using AlCl<sub>3</sub>-dissolved diglyme as displayed in Fig. 1c [5]. The coulombic efficiency was 95% at the 10th cycle. We suggested that in this solution some neutral species of AlCl<sub>3</sub> changed into ionic ones of [AlCl<sub>2</sub>•(diglyme)<sub>2</sub>]<sup>+</sup> and AlCl<sub>4</sub><sup>−</sup>, giving good conductivity (4.06 mS cm<sup>-1</sup>). Since the molar ratio of AlCl<sub>3</sub>:diglyme was 1:5, sizable amount of free glymes should be present. Efforts are being made to reduce the amount of free glymes.

*250 Kuo Kuang Rd., Taichung 40227, Taiwan R.O.C.*

*\*dowwp@dragon.nchu.edu.tw*

Microvia filling of a printed circuit board (PCB) by acidic copper electroplating has been widely used in electronic industry. The filling mode of copper electrodeposition in microvia must be bottom-up form. Moreover, bottom-up filling phenomenon is believed to be related to the properties and interaction of plating additives.<sup>1</sup> Especially, the interaction of three (accelerator, suppressor, leveler) components have significantly effect on copper filling performance.

It was confirmed that soluble anodes (i.e., P-doped Cu anode) have disadvantage when they were used in the acidic copper plating bath. For instance, the shape of the soluble anodes are changeable with operating time, which may causes non-uniform current distribution to form unequal copper thickness on substrate. Therefore, a special functional insoluble anode was used to replace the soluble anode and conventional dimensionally stable anode (DSA) to maintain better bath stability.<sup>2</sup> The disadvantage of soluble anode can be improved by using the novel DSA.

In this work, a plating formula which was composed of chloride ions, suppressor (polyethylene glycol), leveler (quaternary ammonium species) and a novel accelerator instead of bis(3-sulfopropyl) disulfide (SPS). SPS is not appropriate for DSA system because of easy breakdown; therefore, we develop a novel accelerator, ACC, which has a longer lifetime and better performance for acceleration on copper deposition than SPS. Using DSA instead of P-doped Cu anode has another important contribution, that is, SPS reacts with the copper anode to produce Cu(I)-thiolate. The Cu(I)-thiolate is a strong accelerator in the presence of chloride ion. Cu(I)-thiolate will be accumulated in the copper plating bath to destroy the synergy between the suppressor and accelerator. DSA has no this issue because DSA has no copper. Herein, we will show that ACC combining with DSA can perform excellent copper fill in microvia.

# Using Graphene as a Conducting Layer and Barrier Layer for high aspect ratio Through Silicon Via Filling

Wei-Yang Zeng, and Wei-Ping Dow\*

*Department of Chemical Engineering, National Chung Hsing University

[dowwp@dragon.nchu.edu.tw](mailto:dowwp@dragon.nchu.edu.tw)

Traditional process for TSV fabrication is a dry process that includes the following step: (1) formation of vias by reactive ion etching; (2) formation of a SiO<sub>2</sub> isolation liner; (3) deposition of a TiN barrier layer and a copper seed layer; (4) via fill with copper electrodepositing. Herein, we attempt to use graphene to substitute the TiN barrier layer and the copper seed layer for reducing the traditional process procedure.

Graphene materials, including single layer and multi-layer graphene platelet, have recently drawn extensive attention due to their outstanding electrical and thermal properties. Reduction of graphene oxide (GO) is a method to prepare the graphene film. Since GO has a large amount of oxygen functional groups, it can be well dispersed in several solvents and enable it to be coated on a substrate by a chemical grafting method using a wet process.

In TSV technology, the thermo-mechanical fatigue may lead to failure in the TSV interconnects because the coefficient of thermal expansion (CTE) of copper is much higher than that of silicon. The packaging materials with different CTEs will induce large stresses at interfaces. To overcome this problem, we choose graphene sheets to substitute the copper seed layer since the CTE of graphene is closer to silicon than copper. In our research, we reduce the procedure of TSV fabrication using a wet process to simultaneously substitute barrier and seed layer with graphene, and to replace filled copper with filled nickel-tungsten alloy in high aspect ratio TSV. This replacement can result in lower fabrication cost compared with the traditional TSV process.

# Surface Limited Redox Replacement Deposition of Pt Bimetallic Nanostructures

Natasa Vasiljevic, Benjamin Rawlings, Michael Mercer and Zakiya Al Amri  
*H.H. Wills Physics Laboratory, University of Bristol*  
*Tyndall Avenue, Bristol*  
[n.vasiljevic@bristol.ac.uk](mailto:n.vasiljevic@bristol.ac.uk)

Design of highly active Pt bimetallic nanostructures has been of great interest for development of commercially viable catalysts for fuel cells applications [1]. Design of Pt nanostructures with the atomic scale control such as the strained monolayers, Pt- alloys and Pt-clusters has been pursued by variety of methods and on different types of metal systems. The confinement and reduction of the dimensions to few atomic layers coupled with the neighbourhood of Pt to another metal, causes electronic and geometrical effects that can substantially alter the catalytic performance.

One of the most successful approaches that has been shown to produce Pt monolayers with high control of atomic structure is Surface Limited Redox Replacement (SLRR) [2, 3]. This method is based on the replacement of an underpotentially deposited (UPD) layer of a less noble metal by a more noble Pt through irreversible surface-controlled limited redox reaction.

Here in this talk we will describe SLRR based design of different types of Pt-nanostructures on Au and Pd/Au substrates: epitaxial films, alloys and clusters (different size and distribution). The advantages of using SLRR method to design high quality 2D model Pt bimetallic systems will be demonstrated by studies of their electrochemical and catalytic behavior as a function of structure (i.e. film thickness, alloy composition and clusters size i.e. surface coverage). The epitaxial Pt thin films (up to 10 ML thickness) have been grown in one cell configuration using Pb UPD with high efficiency and no surface roughness evolution compared to those grown by SLRR of Cu UPD [4]. The incorporation of Pb UPD sacrificial layer was exploited in the SLRR approach by interrupting replacement reaction at partial coverages to design range of Pt rich 2D  $Pt_x Pb_{1-x}$  alloys. The method has been used to examine alloys adsorption properties (H-UPD, CO) and catalytic behavior during formic acid oxidation changes as a function of composition [5]. Besides the metal UPD (such as Pb and Cu), we have introduced H-UPD as a new deposition sacrificial layer that can be used to design Pt-Pd bimetallic structures with superior activity compared to the pure Pt [6]. Presence of Pt on Pd films showed significant effect on the H-absorption which does not diminish even after several layers of Pt deposition. The same effect has been observed for partial coverage of Pt on the surface suggesting the important role of the Pt-Pd interface. The SLRR approach via Pb UPD and H-UPD have been used to design Pt clusters on Au and Pd/Au with the controlled areal coverage and distribution. The role of UPD layer in the clusters distribution as well as the structure will be presented and discussed.

# Chemical Deposition and Galvanic Replacement of Morphologically Controlled Cu<sub>2</sub>O Nanoparticle Films

Alexander Vaskevich, Mariano Susman, Israel Rubinstein  
*Department of Materials and Interfaces, Weizmann Institute of Science*  
*Rehovot 7610001, Israel*  
*alexander.vaskevich@weizmann.ac.il*

Nanostructured cuprous oxide (Cu<sub>2</sub>O) is an intriguing direct bandgap semiconductor material with potential applications as a UV-Vis light absorber in solar cells, a photocatalyst for the degradation of organic pollutants, a negative electrode in Li-ion batteries, and others.

It is known that the morphology and size of Cu<sub>2</sub>O nanoparticles (NPs) may affect their photocatalytic and light-absorption properties. However, the preparation of Cu<sub>2</sub>O NPs with morphological control has been largely restricted to colloidal syntheses and electrodeposition on conductive substrates.

We have developed an electroless (chemical) deposition (ELD) approach to direct preparation of Cu<sub>2</sub>O nanocrystal (NC) films on substrates, using CuSO<sub>4</sub>-HCHO-Citrate-NaOH solutions.<sup>1</sup> Our method shows a high degree of morphology control (see Figure 1). The average NC size can be varied by controlling the deposition time, while the crystallographic structure is determined by the solution composition (Figure 1). The NC films were studied by SEM, TEM, GIXRD and UV-Vis spectroscopy.

Figure 1. HRSEM images of ELD Cu<sub>2</sub>O NCs on glass substrates, Crystal morphology: (A) complete octahedra, (B) tip-truncated octahedra, (C) truncated octahedra, (D) truncated octahedra, (E) cuboctahedra, (F) tip-truncated cubes, and (G) complete cubes. Scale bars: 200 nm (top), 50 nm (bottom).

The supported Cu<sub>2</sub>O NCs were subjected to galvanic replacement (GR) reactions with metal salts at different pHs.<sup>2</sup> The solution pH in GRRs has been commonly considered an irrelevant parameter; yet, the solution pH plays a major role in GRRs involving metal oxide NPs. We studied Cu<sub>2</sub>O NCs as galvanic replacement (GR) precursors, undergoing replacement by gold and palladium, with the evolving nanostructures showing a strong dependence on the pH of the replacing metal salt solution. The resulting structures strongly depend on the solution pH, showing formation of Cu<sub>2</sub>O NCs decorated with smaller isolated metal (Me) NPs at higher pHs, and uniformly coated Cu<sub>2</sub>O@Me nanoarchitectures at lower pHs. Control of the pH enabled production of different nanostructures, from metal-decorated Cu<sub>2</sub>O NCs to uniformly-coated Cu<sub>2</sub>O-in-metal (Cu<sub>2</sub>O@Me) core-shell nanoarchitectures. The observed improved metal nucleation efficiencies at low pHs are attributed to changes in the Cu<sub>2</sub>O surface charge resulting from protonation of the oxide surface. GR followed by etching of the Cu<sub>2</sub>O cores provided metal nanocages, that collapsed upon drying; the latter was prevented using a sol-gel silica overlayer stabilizing the metal nanocages. Metal-replaced Cu<sub>2</sub>O NCs and their corresponding stabilized nanostructures may be useful as photocatalysts, electrocatalysts and nanosensors.

damian.kowalski@univ-reims.fr

The anodizing is a high-voltage electrochemical conversion process that forms barrier-type oxide layers or nanoporous/nanotubular structures on valve metals and alloys mainly depending on the composition of electrolyte used.[1] The key to achieve the ordered nanoporous/nanotubular structures is a displacement of the film material above the original surface position due to synergistic effect of pits generation (field assisted oxide dissolution), stress generated at the metal-oxide interface including electrostriction and plastic oxide flow switching the growth of the barrier-film to nanotube/nanopore. Typically, the TiO<sub>2</sub> nanotube array formed in organic electrolytes such as glycerol, dimethyl sulfoxide, ethylene-glycol is obtained in the form of close packed structure in which the nanotubes nearly stick together with the tube walls. A fundamentally different nanostructure from that is obtained in diethylene-glycol electrolyte. The nanostructure is characterized by free standing nanotubes separated by an interconnecting space larger than the diameter of nanotubes (Fig. 1).

Herein we report on how to control the synthesis of TiO<sub>2</sub> nanotubes to achieve wide spacing between nanotubes. [2,3] We discuss functional properties of titania nanostructures and report the application of titania as a template material for electrodeposited nanostructures. We compare the template to anodic alumina oxide (AAO) which is one of the most widely used hard template materials; the secondary material is typically deposited in the pores of AAO forming nanowires of desired length and diameter. With TiO<sub>2</sub> nanotubes as a template it is possible to control deposition inside the nanotubes and/or space in between them. The resulting electrodeposited nanostructures are in the form of: nanopore array, inverse nanotube array and nanowires. A general scheme for electrodeposition in TiO<sub>2</sub> nanotubes with synthetic metals be presented. [4]

Fig. 1 SEM top and cross-section views for TiO<sub>2</sub> nanotubes formed at 60V for 16h in diethylene glycol electrolyte containing water content from 2-14 wt. %

# Electrodeposition Process of Ni-Ga Bimetallic Catalyst in BMIm-OTF Ionic Liquid Electrolyte

Jinqiu Zhang, Xing Gu, Peixia Yang, Maozhong An

School of Chemical Engineering and Technology, Harbin Institute of Technology

P.O. Box 1247, No. 92 Xidazhi St., Harbin 150001, China

zhangjinqiu@hit.edu.cn

Ni-Ga bimetallic catalysts could catalyse the synthesis of methanol from CO<sub>2</sub> and H<sub>2</sub>, which was proposed by a computational screening study at first and then has been experimentally confirmed. Ni<sub>5</sub>Ga<sub>3</sub> was thought as the most active composition to take place of conventional Cu/ZnO/Al<sub>2</sub>O<sub>3</sub> catalyst [1, 2]. Compared with chemical synthesis method, electrochemical method is in-situ, convenient, chemical residue-free and easily controllable for catalyst preparation. In a traditional aqueous solutions, Ga is hardly to be electrodeposited because the standard potential of Ga<sup>3+</sup>/Ga is -0.549V is more negative than H<sup>+</sup>/H<sub>2</sub>. However, ionic liquid electrolytes offer a better thermal stability, a wider temperature range and wider electrochemical windows for the deposition of Ga. Cu-In-Ga-Sn thin film was successfully deposited in BMIm-OTF (1-Butyl-3-methylimidazolium trifluoromethanesulfonate) ionic liquid [3].

In this paper, Ni-Ga catalyst was electrodeposited in BMIm-OTF ionic liquid containing nickel chloride and gallium chloride. The electrodeposition and electrochemical measurements were performed using a CHI750D electrochemical workstation. A nickel sheet and a silver wire were used as the reference and the counter electrodes, respectively. The cathodic peak of gallium is at -1.75V (Fig.1a), but its cathodic current is smaller than that of nickel whose cathodic peak at -1.23V (Fig.1b). The co-deposition peak of Ni-Ga is at -1.35V. Micromorphologies, compositions, crystal structures and catalytic properties of Ni-Ga catalysts electrodeposited at different potential are studied. It can be seen from Fig.2 that the particle sizes are around 100nm.

Fig.1 The 5<sup>th</sup> cyclic voltammetry curves of electrolytes containing (a) 20mmol/L gallium chloride, (b) 50mmol/L nickel chloride and (c) 50mmol/L nickel chloride and 20mmol/L gallium chloride.

Fig.2 SEM images of Ni-Ga catalysts electrodeposited at -1.5V (vs. Ag) for 60min at 70°C.

# Using Cu Nanoparticles as Catalysts of Electroless Copper Deposition for Metallization of a Printed Circuit Board

Yao-Lin Tsai and Wei-Ping Dow\*

Department of Chemical Engineering, National Chung Hsing University

250 Kuo Kuang Rd., Taichung 40227, Taiwan, R.O.C.

\*dowwp@dragon.nchu.edu.tw

In recent years, electroless deposition process is commonly used for the metallization of through holes of printed circuit boards (PCBs). Up to now, Sn/Pd colloid process is used to initiate the Cu electroless deposition on the glass fiber and epoxy resin of PCB. However, Pd is very expensive and the residual Pd need to be removed from the epoxy resin after copper electroplating and patterning to prevent shortage between two copper lines. This step will largely increase the process cost. Based on this reason, we introduce a wet process to replace the Sn/Pd colloid process. We made use of a flexible substrate to synthesize copper nanoparticles (CuNPs). The mean particle size of the CuNP is smaller than 10 nm and their size distribution varies from 4 to 6 nm. Therefore, they perform a highly catalytic activity on Cu electroless deposition. Two critical technologies of the CuNP synthesis need to overcome. One is anti-oxidation of CuNPs, the other is the cost issue of the flexible substrate. We proposed solutions to overcome the two issues. The CuNPs were characterized by UV-Vis, FE-SEM, HR-TEM and XRD. The results show that CuNP can replace Sn/Pd colloid to act as the catalyst for copper electroless deposition on both glass fiber and resin materials. The back light and thermal reliability tests of the through hole of a PCB can pass the industrial specification.

# Combining Superfill and Leveling Capabilities: New Hybrid Polymers for Advanced Damascene Applications

N.T.M. Hai<sup>1</sup>, V. Grimaudo<sup>1</sup>, P. Moreno-García<sup>1,2</sup>, D. Lechner<sup>1</sup>, F. Stricker<sup>1</sup>, A. Riedo<sup>2</sup>, P. Wurz<sup>2</sup>, and P. Broekmann<sup>1</sup>

[peter.broekmann@dcb.unibe.ch](mailto:peter.broekmann@dcb.unibe.ch)

The on-chip metallization of vias and trenches for state-of-the-art microprocessor fabrication relies on an additive-controlled Cu deposition process (Damascene electroplating). The classical direct current (DC) approach of Damascene plating is based on the use of a three-component additive package commonly consisting of a suppressor polymer (e.g. polyalkylene glycols, PAGs), its specific anti-suppressor (bis-(sodium-sulfopropyl)-disulfide, SPS) and a so-called leveler.

In this contribution we demonstrate a successful bottom-up fill of single Damascene test features by using a two-component additive package consisting of SPS (bis-(sodium-sulfopropyl)-disulfide) and Imep polymers (polymerizates of imidazole and epichlorohydrin). Besides the successful feature fill a remarkable leveling effect is observed. Obviously, the Imep additive combines bottom-up fill capabilities with leveling characteristics in one single polymer component. These unique hybrid properties of the Imep are rationalized on the basis of an extended N-NDR (N-shaped negative differential resistance) being present in the linear sweep voltammogram of the SPS/Imep additive system during Cu electrodeposition (Figure 1).<sup>[1]</sup>

A serious drawback of classical Damascene leveler concepts is the high and non-uniform additive incorporation into the copper deposit that limits its post self-annealing (recrystallization). We will demonstrate that copper films deposited in the presence of Imep/SPS additive package are largely contamination-free thus allowing a fast post-deposition recrystallization. For the quantification of (trace) contaminants in the electroplated copper films we make use of a newly developed Laser Ionization/Ablation Mass Spectrometry (LIMS) depth profiling approach. With this technique even a sub-nm depth resolution can be achieved which is a crucial prerequisite for the identification of contaminations localized at Cu grain boundaries.

# Interplay of Different Reaction Pathways in the Pulsed Galvanostatic Deposition of ZnO

M. Stumpp, T. H. Q. Nguyen, C. Lupo, D. Schlettwein  
*Justus-Liebig-Universität Gießen, Institut für Angewandte Physik*  
*Heinrich-Buff-Ring 16, 35392 Gießen, Germany*  
*schlettwein@uni-giessen.de*

Zinc oxide ZnO is a promising electrode material for the application in dye-sensitized solar cells (DSCs) and in devices for transparent electronics. Electrochemical deposition is an environmentally-friendly and energy-efficient technique for the deposition of crystalline ZnO and as no subsequent annealing is required, films can be prepared on temperature-sensitive substrates.

In the present work, aqueous solutions of  $\text{Zn}(\text{NO}_3)_2$  were used for electrodeposition of ZnO on gold substrates in micrometer dimensions under pulses of controlled current. Potential-time curves were acquired dependent on current density and pulse times  $t_{\text{on}}$  (current) and  $t_{\text{off}}$  (rest potential). Three significant stages (see scheme) were observed. Scanning electron and confocal laser microscopy analysis revealed a correlation between a successively completed coverage of the Au electrode by ZnO in stage I and an abrupt transition (stage II) of the deposition and rest potential to less negative values in stage III in which the characteristic growth mode of ZnO was observed. The deposition time at which such a transition was detected depended not only on the amount of deposited ZnO but also on the current density during electrodeposition and on the electrode geometry. An influence of different diffusion profiles of the reacting ions was thereby indicated. In order to elucidate the role of different redox reactions in the course of electrodepositions of ZnO, measurements were also carried out in various reference electrolytes. The three stages in the potential were only seen for pauses which were equal or longer than the current pulse. The significance of each stage and the corresponding reaction is discussed for the preparation of ZnO films completely covering an electrode surface to optimize the deposition for future applications in electronic devices or in DSCs.

Scheme 1: Dominating reactions (continuous arrows) and side reactions (dotted arrows) during a pulse ( $t_{\text{on}}$ ) and pause ( $t_{\text{off}}$ ) at the three stages (I-III) of deposition. Poisoning of the ZnO surface for subsequent crystallization of ZnO (double red line) by reaction products (also red) formed on the exposed metal surface was concluded from the observed changes in deposition potential.

If depositions from nitrate-based deposition solutions are aimed at to attain thin compact and pinhole-free semiconductor films as needed, e.g., in some electronic device applications, depositions in short pulses with sufficiently long pauses promise to be most successful and reliable. Use of a galvanostatic deposition mode to provide a fixed growth rate and a substrate even with a rather high overpotential for the reactions underlying the deposition can be of great use in this context because the established potential and its abrupt, easily detected transition can serve as a safe indicator for a successful coating of the substrate.

# A Ni - 4,4'-bipyridine - Ni single-molecule electrochemical transistor

Nanoscale electrochemistry not only enables the preparation of 4,4'-bipyridine (44BP) single-molecule junctions with oxide-free Ni electrodes, but also allows for control of their electrical transport by non-redox electrochemical gating<sup>1</sup>. The single-molecule junctions are prepared by the scanning tunneling microscope break junction (STM-BJ) technique<sup>2</sup>, which involves bringing a Ni STM tip into contact with an electrodeposited Ni film, then withdrawing the former to create first a nano-constriction exhibiting conductance quantization and subsequently a nano-gap, across which the 44BP can adsorb. The 44BP is dissolved in a pH 3, 0.05 M Na<sub>2</sub>SO<sub>4</sub> aqueous solution and the potentials of tip and substrate are controlled relative to a polypyrrole (PPy) quasireference electrode ( $\sim +0.31$  V with respect to saturated calomel).

In this presentation, we compare the conductances of Ni - 44BP - Ni and Au - 44BP - Au single-molecule junctions measured at a constant tip-substrate bias potential of 0.1 V, while varying the potential of the substrate. For both Ni and Au, the conductance increases as the substrate is made more negative and the metal Fermi level is raised relative to the 44BP frontier orbitals (**Figure 1**). This is the behaviour expected for transport via the 44BP lowest unoccupied molecular orbital (LUMO).

**Figure 1:** Conductance as a function of substrate potential for 4,4'-bipyridine (44BP) single-molecule junctions with different electrodes. HC and LC stand for High Conductance and Low Conductance respectively.

Note that not only is the measured conductance greater for single-molecule junctions with Ni electrodes, but so is the rate of change of conductance with substrate potential. As the substrate potential controls the electrochemical gating, this means that Ni-44BP-Ni is a more effective single-molecule electrochemical transistor than Au-44BP-Au. A further difference between Ni and Au lies in the fact that only one conductance value is measured for Ni-44BP-Ni, whereas two (HC and LC) are measured for Au-44BP-Ni.

Density functional theory calculations throw an interesting light on these results. They not only provide an explanation for the higher conductance of Ni-44BP-Ni single-molecule junctions, but also for the existence of only a single conductance peak. Of particular interest is the fact that they provide strong evidence that the current through the Ni-44BP-Ni device is highly spin-polarized.

# Oxygen Bubble Templated Anodic Deposition of Porous PbO<sub>2</sub>

M. Musiani, S. Cattarin, N. Comisso, P. Guerriero, L. Mattarozzi, E. Verlato

*IENI CNR*

*Corso Stati Uniti 4, 35127 Padova*

*m.musiani@ieni.cnr.it*

The hydrogen bubble templated electrodeposition of porous metals and alloys has been extensively investigated, in recent years [1]. In this process, electrolyses performed at high current density cause simultaneous metal ions reduction and hydrogen evolution, leading to the formation on the cathode of deposits with a bimodal porosity. The deposits exhibit interconnected pores with quasi-circular mouths and typical diameters of tens of microns, due to the metal growth around the hydrogen bubbles, and nano-scale, irregular pores separating the assemblies of metal dendrites that constitute the metal layer.

In the present communication, we report on a preliminary investigation aimed at realizing an analogous process at the anode: the oxygen bubble templated anodic deposition of porous PbO<sub>2</sub>. Owing to possible uses of PbO<sub>2</sub> in energy storage and as inexpensive anode material, obtaining layers with a high surface roughness factor may be interesting [2, 3].

In typical experiments, high current densities (up to 4 A cm<sup>-2</sup>) were imposed to rotating disc anodes (usually Ni) in various deposition baths containing Pb(II) salts dissolved either in concentrated NaOH or in mildly acid solutions. Oxidation of Pb(II) ions to PbO<sub>2</sub> and oxygen evolution occurred simultaneously. Porous structures were obtained in most cases, but the void volume fraction was lower and the connections between neighbouring pores were less numerous in PbO<sub>2</sub> layers than in most metal layers described in the literature. None of the porous PbO<sub>2</sub> layers prepared so far exhibited a nano-scale porosity comparable to that of metal deposits. This result is ascribed to different electrocrystallization kinetics of PbO<sub>2</sub>, as compared to metals, and to its very low tendency to undergo dendritic growth. Work is in progress to optimize the deposit morphology and accurately measure their surface roughness factor.

Porous PbO<sub>2</sub> deposits obtained at 2 A cm<sup>-2</sup> from a lead sulfamate bath

# Electrodeposition of Nanowires and Nanostructures from Supercritical Fluids

P. N. Bartlett

*University of Southampton*

*Chemistry, Highfield, Southampton, SO17 1BJ, UK*

*pnb@soton.ac.uk*

Supercritical fluids are potentially highly attractive media for the electrodeposition of metals and semiconductors into complex nanostructures [1]. Supercritical fluids readily penetrate porous and nanoporous structures because they have essentially zero surface tension. They also have low viscosities and hence show enhanced mass transport rates. Depending on the choice of electrolyte and solvent they can also have a wide electrochemical window. However these advantages do not come without several disadvantages; their generally low dielectric constants, and the necessity to work in sealed systems at elevated temperature and pressure. For these reasons the field of electrodeposition from supercritical fluids is still relatively unexplored with very little published work on electrodeposition from single phase supercritical systems.

In order to explore the possibilities of using electrodeposition from supercritical fluids to make sub 20 nm nanostructures and nanostructured devices we have focused on the electrodeposition of a range of p-block elements (Ga, In, Ge, Sn, Pb, Sb, Bi, Se and Te) from supercritical difluoromethane [2]. In this lecture I will present results of our latest results on electrodeposition of these elements from supercritical difluoromethane, the characterization of the electrodeposited materials, and work on the electrodeposition of sub-20 nm nanowires.

**Figure.** SEM image of 13 nm Te nanowires produced by electrodeposition through an anodic alumina template using supercritical difluoromethane.

# In situ Scanning Tunneling Microscopy Imaging Self-Assembled Monolayers of Mercaptoacetic Acid and Cupric Ion on Au(111) Electrode

Shuehlin Yau\*

*Department of Chemistry, National Central University, Jhongli, Taiwan 320, ROC*

Voltammetry and scanning tunneling microscopy (STM) were used to study the coadsorption of mercaptoacetic acid (MAA) and cupric ions ( $\text{Cu}^{2+}$ ) on Au(111) electrode from 0.5 M sulfuric acid + 0.8 M  $\text{CuSO}_4$  + 0.03 mM MAA. Irreversibly adsorbed  $\text{Cu}^{2+}$  ions were reduced at 0.27 V first then at -0.2 V (vs. Ag/AgCl), ascribed to the underpotential and overpotential deposition processes, respectively. Counting the amount of charge involved in the stripping peak of the Cu deposit rendered quantification of  $\text{Cu}^{2+}$  ions codeposited with MAA on the Au(111) electrode, which yielded roughly  $7.7 \times 10^{14}$   $\text{Cu}^{2+}$  ions/ $\text{cm}^2$ .

MAA alone and MAA +  $\text{Cu}^{2+}$  were adsorbed in Au(111) -  $(3 \times \sqrt{13})$  and  $(p \times \sqrt{3})$  structures respectively, as shown below. It is likely that  $\text{Cu}^{2+}$  ions were coadsorbed with MAA, although the detailed structure of MAA +  $\text{Cu}^{2+}$  thin film was not clear. Adsorbed  $\text{Cu}^{2+}$  could be imaged by the STM, as seen as protruded linear segments seen in panel (b). They possibly interacted with  $-\text{CCO}^-$  groups of MAA molecules tethered to Au(111) electrode via their  $-\text{S}$  ends. But  $\text{Cu}^{2+}$  ions seemed to move on the electrode surface, which evaded high - quality STM imaging needed to quantify the amount of adsorbed  $\text{Cu}^{2+}$ .

Lowering the potential resulted in marked changes in the surface film, as shown in panel (c). At 0.2 V, Cu UPD commenced, which resulted in restructuring of the thin film. MAA molecules adsorbed on gold electrode now segregated onto the Cu deposit. The electrode surface was mostly disordered but local linear segments were imaged. Lowering potential to more negative values further caused changes of the thin film, resulting from the charged state of Cu adatoms and interaction between MAA molecules. They returned to the Au(111) electrode once the Cu deposit was oxidized at  $E > 0.4$  V. However, the film likely consisted of MAA +  $\text{Cu}^{2+}$  was organized differently from those seen at the pristine sample.

Three STM images collected with Au(111) electrode dosed with 30  $\mu\text{M}$  MAA (a), 30  $\mu\text{M}$  MAA + 0.88 M  $\text{Cu}^{2+}$  (b), and UPD of Cu at 0.2 V in 0.1 M  $\text{H}_2\text{SO}_4$  (c).

# Room Temperature Electrodeposition of Metallic Magnesium from Ethylmagnesiumbromide/Tetrahydrofuran and Ionic Liquid Mixtures

Lu Chen, Mike. Horne, Alan M. Bond, Jie Zhang  
School of Chemistry, Monash University  
Wellington Road, Clayton, Vic 3800, Australia  
Lu.chen@monash.edu

The deposition process, nucleation-growth mechanisms and magnesium speciation in deposition of metallic magnesium on an aluminium electrode at room temperature are reported using mixed deposition medium composed of 0.095 M ethylmagnesiumbromide/tetrahydrofuran (EtMgBr/THF) and 0.54 M ionic liquids such as:

1-Butyl-1-methylpyrrolidinium tris(pentafluoroethyl)trifluorophosphate (Py<sub>14</sub>FAP),  
1-Butyl-1-methylpyrrolidinium bis(trifluoromethylsulfonyl)imide (Py<sub>14</sub>TFSI),  
1-Butyl-1-methylpyrrolidinium bis(fluorosulfonyl)imide (Py<sub>14</sub>FSI),  
1-Butyl-1-methylpyrrolidinium tetrafluoroborate (Py<sub>14</sub>BF<sub>4</sub>),  
1-Butyl-1-methylpiperidinium bis(trifluoromethylsulfonyl)imide (PipTFSI),  
Ethyltrimethylpropylammonium bis(trifluoromethylsulfonyl)imide (N<sub>1123</sub>TFSI),  
Diethylmethyl(2-methoxyethyl)ammonium bis(trifluoromethylsulfonyl)imide (DEMETFSI).

Cyclic voltammetric results showed an electrochemically reversible Mg/Mg<sup>2+</sup> process in the case of [FAP]<sup>-</sup> and [TFSI]<sup>-</sup> based ionic liquids, but not for the [FSI]<sup>-</sup> and [BF<sub>4</sub>]<sup>-</sup> based ones. The difference is ascribed to IL dependent magnesium speciation. Analysis of chronoamperometric data revealed that in the presence of Py<sub>14</sub>FAP and PipTFSI, magnesium nucleation occurred via a 3D instantaneous nucleation and diffusion controlled semi-spherical growth model.<sup>[1]</sup> However, in the presence of Py<sub>14</sub>TFSI, DEMETFSI and N<sub>1123</sub>TFSI, deviations from this model are evident. Practical applications used a deposition media based on 90% of 1 M EtMgBr/THF mixed with 10% (v/v ratio) of ionic liquids. Deposition parameters such as current density and charge density influenced deposit appearance, crystallite size and preferred orientation. Py<sub>14</sub>FAP was found to be the most favourable IL for practical applications.

Figure 1: Cyclic voltammograms measurements on an aluminium electrode (0.0254 cm<sup>2</sup>) at a scan rate of 100 mV s<sup>-1</sup> from deposition medium containing 0.095 M EtMgBr/THF and 0.54 M Py<sub>14</sub>BF<sub>4</sub>, Py<sub>14</sub>FSI, Py<sub>14</sub>TFSI and Py<sub>14</sub>FAP. (Left) Figure 2: XRD characterization of magnesium electrodeposits from an aluminium substrate (0.24 cm<sup>2</sup>) in deposition medium containing 90% of 1M EtMgBr/THF and 10% (v/v ratio) of Py<sub>14</sub>FAP, Py<sub>14</sub>TFSI, PipTFSI, N<sub>1123</sub>TFSI and DEMETFSI, at constant deposition current density (11.7 mA/cm<sup>2</sup>) and charge density (42.24 C/cm<sup>2</sup>) (Right).

Chirality is a fundamental problem in chemistry and life science, and chiral catalysts play the most important scientific and technological roles in modern industry. In this sense, how to fabricate chiral catalysts is still an open question with important fundamental and technical interest.

Mogi has first found the appearance of the enantiomorphic activity of the electrodes deposited in vertical magnetic fields [1]. Then, the following studies clarified that the chiral activities of magnetoelectrochemically deposited surfaces are attributed to numerous chiral screw dislocations corresponding to 2D and 3D nuclei, which are created by minute vortexes termed micro- and nano-MHD flows, respectively, activated by magnetic field and macroscopic rotation [2].

**Electrochemical instability:** In electrodeposition, crystal nuclei are classified into two types, i.e., 2D nucleus with a 100  $\mu\text{m}$  scale of length and 3D nucleus with a 0.1  $\mu\text{m}$  scale of length. The former is activated in electric double layer, and the latter in diffusion layer. Then, 2D nuclei unstably develop under non-specific adsorption of ions at Helmholtz layer, but stably repeat birth and death under specific adsorption of ions such as chloride ion. On the other hand, 3D nuclei always develop in an unstable mode. As a result, in the absence of specific adsorption, chiral micro-MHD vortexes from 2D nuclei are dominant over the electrode surface, yielding L-active and D-active catalysts dependent on the direction of magnetic field. However, after adding chloride ions, the vortexes with 2D nucleation are suppressed, and only chiral nano-MHD vortexes from 3D nuclei survive, so that the situation is drastically changed.

**Effect of vertical MHD flow:** In electrodeposition under a vertical magnetic field  $B_0$ , as shown in Fig. 1, a macroscopic tornado-like vortex termed vertical MHD flow with an angular velocity  $\Omega$  emerges. On the electrode surface, iso-entropic particles, i.e., ionic vacancies are stoichiometrically produced, forming a non-viscous layer without friction. Due to disappearance of micro-MHD vortexes by adding chloride ions, this layer rotates with the vertical MHD flow, and the nano-MHD vortexes on the 3D nuclei receive precessions, so that other vortexes except for a specific rotational direction are prohibited. Since the direction is determined by the sign of the product  $B_0\Omega$ , irrelevantly to the direction of magnetic field, only chiral vortexes with anticlockwise (ACW) rotation arise, yielding clockwise (CW) screw dislocations. In view of the mirror-image relationship between enantiomorphic catalyst and its reagent, the electrode surface will always acquire L-activity.

Figure 2 shows the chloride effect, i. e., a chiral CW dislocation under ACW vortex, whereas as shown in Fig. 3, in the absence of the vortex, achiral surface with ACW and CW dislocations emerges.

Fig. 1 Vertical MHD flow.

Fig. 2 CW chiral screw dislocation.

Fig. 3 ACW and CW screw dislocations.

# Characterization of the microstructure of reservoirs using electrodeposition method

Jianming Li, Xu Jin, Xiaoqi Wang, Liang Sun, Songtao Wu

*Petroleum Geology Research and Laboratory Center, PetroChina Research Institute of Petroleum Exploration & Development (RIPED)  
No. 20 Xueyuan Road, Haidian District, Beijing, 100083, P.R. China  
lijm02@petrochina.com.cn*

Reservoir microscopic pore structure (Figure 1) refers to the size and geometry of the reservoir rock pores and throats, and their distribution and interconnected relationships. Reservoir microscopic pore structure directly affects the reservoir porosity, storage, and permeability, the research on reservoir microscopic pore structure can help to evaluate the reservoir, find out reservoir distribution law, and even improve the productivity and recovery ratio of oil and gas. Therefore, how to accurately characterize the reservoir microscopic pore structure received more and more attention.

The Computed Tomography (CT) scanning technologies, including nano-CT, micro-CT, and industrial-CT, are widely used in the reservoir microscopic pore structure characterization. However, the micro-CT can only characterize micron pore structure with the maximum resolution of 0.7 micron; the resolution of nano-CT is higher than micro-CT, with the maximum resolution of 50 nm. In addition, the observing area of nano-CT is small, about 60 microns, which results higher cost of instrument operation and sample preparation. With the progress of oil and gas exploration and development, it has been found that there were abundant nanoscale pores and throats remained in the shale, tight sandstone, and other unconventional reservoirs. Due to the maximum resolution of CT scanning is 50 nm, the CT scanning technology is difficult to meet the needs of characterization of unconventional reservoirs.

In this presentation, we first combined the electrochemical deposition and SEM methods to characterize reservoir microscopic pore structure. As a result, we could directly observe the 3D microstructure of reservoirs smaller than 50 nm with large observing area (Figure 2). In addition, the connected pores and throats of reservoirs could be calculated.

Figure 1. The typical microscopic pore structure of reservoir.

Figure 2. The typical observed 3D microstructure of reservoir.

Supercritical fluid is any substance at a temperature and pressure above its critical point. Surface tension of supercritical fluid is extremely low and the physical properties can be easily adjusted by controlling pressure and temperature. Therefore, supercritical CO<sub>2</sub> (sc-CO<sub>2</sub>) is applied in electrodeposition of materials to overcome problems encountered in continuous miniaturization of the electronic components. However, CO<sub>2</sub> is non-polar and has very low electrical conductivity. Thus, a surfactant is used to form emulsions composed of an aqueous electrolyte, sc-CO<sub>2</sub>, and the surfactant [1].

Materials electrodeposited with sc-CO<sub>2</sub> emulsified electrolyte (SCE) are reported to have properties very different from that electrodeposited under conventional conditions. Grain refinement and surface smoothening are reported for Ni and Cu films electrodeposited with the SCE [1-3]. Grain size of the Ni electrodeposited with the SCE could be less than 10 nm [2]. Most interestingly, single crystal or twin crystal structure of Cu are observed when the SCE is applied in filling of Cu into the nano-holes [3].

When the SCE is applied in cathodic deposition of TiO<sub>2</sub> films, deposited TiO<sub>2</sub> films are porous, and the films are composed of nano-scale primary particles and aggregates of the primary particles [4]. Grain coarsening and increase in size of the primary particles are observed for TiO<sub>2</sub> electrodeposited with the SCE when compared with the conventional case. ZnO mesocrystals are obtained when the SCE is applied in cathodic deposition of ZnO, [5].

TiO<sub>2</sub> obtained from cathodic deposition is usually amorphous. An additional heat treatment process, such as 400°C for 1 hr, is required to have crystalline TiO<sub>2</sub>. This heat treatment process would increase the process time and affect properties of the substrate and morphology of the TiO<sub>2</sub> films. In a recently study on cathodic deposition of TiO<sub>2</sub> films with the SCE, crystallinity of the TiO<sub>2</sub> was found to be significantly improved with increase of pressure from atmospheric pressure to 35 MPa. Anatase TiO<sub>2</sub> was obtained at a pressure higher than 25 MPa without any additional heat treatment process. The effect of pressure on crystallinity of TiO<sub>2</sub> deposited is named hydrobaric effect, because the deposition only takes place in the aqueous phase in the emulsions, and the effect is similar to the hydrothermal effect in some degree. This is the first report on hydrobaric effect, which is the effect of pressure on chemical reaction conducted in an aqueous solution. We believe the hydrobaric effect can be applied to remove or reduce high-temperature needed in some chemical processes.

A reference electrode is required to identify the electrochemical reactions take place and precisely control the electrochemical reactions in the SCE. However, there is no reference electrode for the SCE because of the high pressure and the complex conditions in the emulsions. In order to solve this problem, the idea of pseudo reference electrode is used. A palladium-hydride based material is found to be stable to provide potential readings close to a hydrogen reference electrode in the SCE [6]. With the newly developed reference electrode, more fundamental studies can be conducted to clarify effects of the SCE, and design of new functional materials with improved properties can be realized.

# Extremely Fast Filling by V-shape TSV and Cu(I)thiolate accumulation

Kazuo Kondo, Van Ha, Masayuki Yokoi

Osaka Prefecture University

1-1, Gakuen-cho, Naka-ku, Sakai, 599-8531, Japan

kkondo@chemeng.osakafu-u.ac.jp

Conventional Through Silicon Via(TSV) filling requires about 30 minutes(1-3) and have columnar TSV shape. A new conical(V-shape) TSV realize the extremely fast TSV filling of 5 minutes. A  $90\text{mA}/\text{cm}^2$  ultra high current density is applied, if compared to the less than  $10\text{mA}/\text{cm}^2$  conventional columnar TSV. The accelerator of Cu(I)thiolate cuprous complex form preferentially at the V-shape TSV bottom and realize this extremely fast 5 minutes.

## Results

1. Figure 1(a) shows the cross section of V-shape TSV. The TSV diameter is  $6\mu\text{m}$  and the depth is  $25\mu\text{m}$ . This TSV is filled with 5 minutes with  $90\text{mA}/\text{cm}^2$  of on-time of pulse reverse current(b).

2. The ring current of the rotating ring disk electrode for the cathodic region has been measured by T.Hayashi(4). With additives of SPS and Chloride, ten times more ring current is obtained if compared to without additive which J.White(5) have reported. T.Hayashi's ring current indicates that enough amount of cuprous is formed with the cathode.

3. The reaction rate from cupric to cuprous( $k_1$ ) is  $2 \times 10^{-4}$  and that from cuprous to copper( $k_2$ ) is 130(6). The huge reaction rate of  $k_2$  indicates once the cuprous forms it very quickly reduces to copper. The  $k_1$  is the rate determining step.

4. Figure 2 shows the role of cuprous and chloride and SPS additives. The chlorides adsorbs on the copper. These chlorides form electron bridges and reduce cupric to the cuprous, which fasten the rate determining step of  $k_1$ . These electron bridges occur everywhere on the copper. At the same time the chloride reduces the SPS to thiolate(monomer of SPS) and forms accelerating complex of Cu(I)thiolate. This Cu(I)thiolate releases the cuprous. If the Cu(I)thiolate is accumulated at the TSV bottom, the Cu(I)thiolate preferentially release the cuprous at the TSV bottom. Since the reaction rate from cuprous to copper,  $k_2$ , is huge the cuprous accelerates the TSV bottom.

5. Figure 3 shows the flow patterns by the numerical fluid dynamics computations with the columnar and V-shape TSV.

Fig.3 Flow patterns by numerical fluid dynamics computations with columnar(a) and V-shape(b) TSVs.

Fig1 Cross sections of V-shape TSVs. a; without filling, b; with filling

Fig.2 Role of Cu(I)thiolate on via bottom acceleration.

V-shape TSV. The upper end is the TSV mouth and lower end is the bottom. In Fig3a, a large vortex form at the TSV mouth for the columnar TSV. Two vortexes exist under this large vortex, however, the vortex deceases at the middle of the TSV. For the V-shape TSV of Fig.3b, a large vortex form at the TSV mouth and this vortex is larger than a. Three vortexes connects under this large vortex and the vortex continue to exist at 1/5 of TSV from the bottom. The vortex rotate the electrolyte within the vortex and the vortex accumulates the Cu(I)thiolate. Hence the vortex preferentially releases the cuprous at the V-shape TSV bottom. Since the reaction rate from cuprous to copper,  $k_2$ , is huge, the V-shape TSV TSV preferentially accelerates the TSV bottom. This is the reason why the ultra high current density of  $90\text{mA}/\text{cm}^2$  is applied without forming voids.

# Investigation Nitrogen Heterocyclic Compounds as Levelers for Electroplating Cu Filling by Electrochemical Method and Quantum Chemical Calculation

Zenglin Wang\*, Shaojun Ren, and Zhanwu Lei

School of Chemistry and Chemical Engineering, Shaanxi Normal University,  
Xi'an 710062, China,  
E-mail: wangzl@snnu.edu.cn

Leveler, as an indispensable role, improves the distribution of the current density and enhances the bottom-up filling performance. However, only some quaternary ammoniums cations as the levelers have been studied<sup>1</sup>. In this work, six nitrogen heterocyclic compounds (NHCs) bearing different functional groups were investigated as potential levelers for bottom-up filling.

From Fig.1, it was found that the cathodic potential shifted positive rapidly ( $\Delta\phi = 51.4$  mV) or changed little with an addition of 2-MPD or MPC, which indicated that 2-MPD and MPC had no inhibition for the Cu deposition. By contrast, the cathodic potential shifted negative rapidly with an addition of AHMP, HMMP, DPT, or 2-MP, which indicated that these NHCs had inhibition for the Cu deposition, and the inhibitive strength of 2-MP was the strongest ( $\Delta\phi = 106.0$  mV).

The potential difference ( $\Delta\eta$ ) can be used as an indicator to judge the bottom-up filling of electroplating copper solution<sup>2</sup>, but the bottom-up filling capability of the solution was not evaluated quantitatively by electrochemical measurement, and had to be determined by cross-sectional images after the electroplating filling. However, the deposition rates of electroplated Cu on the surface and at the bottom could be simulated by a Cu rotating disk electrode with different rotating speeds, and were direct relative to the coulomb value of Cu stripping peaks (Q) in the CV measurements. So, we proposed a relationship between the supper filling capability (SFC) and Cu stripping quantity,  $C = Q_{100\text{rpm}} / Q_{1000\text{rpm}}$ , where  $Q_{100\text{rpm}}$  and  $Q_{1000\text{rpm}}$  were corresponding coulomb value of Cu stripping peaks measured at 100 rpm and 1000rpm, respectively. The SFC was positively associated with the filling performance of the microvias, and the high SFC value was conducive to improve the filling performance and to reduce surface thickness of plated Cu film.

Fig. 1 Cross-sectional OM images of microvias with 1 ppm NHCs: (a) 2-MPD, (b) MPC, (c) AHMP, (d) HMMP, (e) DPT, (f) 2-MP

Furthermore, the absorption ability and active functional groups of NHCs were analyzed by quantum chemical calculations. The absorption ability of NHCs was negative correlation with energy gap ( $\Delta E$ ), and the  $-SH$  and  $=S$  groups in the NHCs were the most active reaction sites for surface absorption on Cu surface, which **was** differ from conventional nitrogen active site in quaternary ammoniums. In addition, the scanning electron microscope and X-ray diffraction results indicated that the uniformity and brightness of the electroplated Cu film were improved by an addition of AHMP, HMMP, DPT, and 2-MP the duo to a significant change of the Cu crystalline orientation in plating deposition.

e-mail: mogi@imr.tohoku.ac.jp

Studies of chiral surface formation in deposition and crystal growth processes are significant not only in pharmaceutical catalysis but also in the homochiral molecular evolution on early earth. Electrodeposition in magnetic field (magneto-electrodeposition; MED) was found to produce enantioselective metal surfaces for amino acids [1-4]. However, the previous MED experiments were conducted with potentiostatic modes, and the exploration of MED condition has not been sufficient for the understanding of chiral formation mechanism. Here we show the chiral behaviors of Cu film surfaces prepared by galvanostatic MED.

The Cu films were electrodeposited on a Pt disc electrode at constant currents of  $-4$  -  $-22$  mA cm<sup>-2</sup> in a 50 mM CuSO<sub>4</sub> aqueous solution containing 0.5 M H<sub>2</sub>SO<sub>4</sub>. The total passing charge was 0.4 C cm<sup>-2</sup> in all the MED experiments, and the film thickness was approximately 150 nm. The electrochemical cell was placed in the bore center of a cryocooled superconducting magnet, and the magnetic field of 5 T was applied parallel (+5T) or antiparallel (-5T) to the faradaic currents.

The MED films were used as electrodes, and their chiral behaviors were examined using voltammetric measurements of alanine. Fig. 1 shows voltammograms of alanine enantiomers on the Cu +5T-film electrode, which is prepared at a deposition current of  $-11$  mA cm<sup>-2</sup>. The chiral behavior is observed in the oxidation current difference between the enantiomers: The peak current of D-alanine is greater than that of L-alanine. Such chiral behavior is termed D-activity.

We examined the chiral behavior of the +5T-film and -5T-film electrodes prepared at various deposition currents. To evaluate the chirality in voltammograms, an enantiomeric excess (*ee*) ratio can be defined as  $ee = (i_p^L - i_p^D) / (i_p^L + i_p^D)$ , where  $i_p^L$  and  $i_p^D$  represent the peak currents of L- and D-alanines, respectively. The positive sign of the *ee* ratio represents L-activity, and the negative one represents D-activity. Fig. 2 shows the *ee* ratios versus the deposition currents for the +5T-film and -5T-film electrodes and that the chiral sign depends on both the electrodeposition current and the polarity of magnetic field. Furthermore, we found that the specific adsorption of chloride ions on the surfaces causes drastic influence on the chiral formation and that such influence depends on the chloride concentration. At the certain concentrations chiral symmetry breaking was observed for the polarity of magnetic field. These new findings are discussed on the basis of magnetohydrodynamic vortices and the rate-determining steps in electrodeposition.

With the evolving technology, the frame mounted design of electronic components has increasingly become high-density, which leads to the electronic elements that are inevitably vulnerable to electromagnetic interference and then affect other electronic products' functions. The solution is to use well conductive material that operates the shielding process. The material includes metals and conductive polymers which are common sources of the protective materials in dealing with the main conductive surface. Although this masking method has been widely recognized, several problems are still observed in practice, including the vulnerability to scaling, abrasion, corrosion and process load.

In this study, we adopt Ni-Fe alloy film as the shielding material and manufacture it by electroplating. We intend to explore the effects of plating solution composition, plating parameter and plating additives on structural strength and magnetic properties of the Ni-Fe alloy film. In electroplating, plating additives play important roles. The results suggest that various additives lead to different crystalline orientations, grain sizes, and surface roughness. A correlation between the plated structure and the magnetic properties is studied. Additionally, anti-corrosion is improved by doping a few boron in the film. The ultimate goal of the study is to meet the requirements of electronic industry in manufacturing Ni-Fe alloy with high permeability and good corrosion resistance.

# Amperometric Detection of Bilirubin via A Room-Temperature Ionic Liquid Imprinted Polymer Composite Electrode

Mei-Jywan Syu\*, Yan-Di Tseng

Department of Chemical Engineering, National Cheng Kung University

No. 1, University Rd., Tainan, Taiwan 701

syumj@mail.ncku.edu.tw syumei2014@gmail.com

Bilirubin is a metabolite of hemoglobin. The concentration of bilirubin in serum is always regarded as an important physiological index for the liver-related disease. In this work, the molecularly imprinted polymer (MIP) with the room-temperature ionic liquid (RTIL) and bilirubin template molecule was fabricated onto the surface of the Au electrode. Both methacrylic acid (MAA) and ethylene glycol dimethyl acrylate (EGDMA) were used as the functional monomers. EGDMA was also used as the crosslinker. 1-Butyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide ([BMIM][TF<sub>2</sub>N]) was the chosen RTIL. Together with bilirubin, the bilirubin-imprinted [BMIM][TF<sub>2</sub>N]-poly(MAA-co-EGDMA) ([BMIM][TF<sub>2</sub>N]-poly(MAA-co-EGDMA) composite) was synthesized onto the Au surface. The SEM images showed that the average thickness of the RTIL-imprinted polymeric film was approximately 1.98  $\mu\text{m}$ . Most of the imprinted bilirubin template molecule could be removed from the imprinted [BMIM][TF<sub>2</sub>N]-poly(MAA-co-EGDMA) film after being extracted properly. Consequently, the specific binding cavity for bilirubin molecules was created after the extraction was applied to the polymer film.

RTIL could enhance the amperometric signal of the MIP electrode. The imprinting factor of  $5.52 \pm 0.09$  and the detection sensitivity of  $0.367 \pm 0.019 \mu\text{A}/\text{cm}^2/\text{mg}/\text{dL}$  were achieved, respectively, from the imprinted [BMIM][TF<sub>2</sub>N]-poly(MAA-co-EGDMA) fabricated Au electrode. The RTIL-MIP electrode is able to detect bilirubin in the low concentration ranging from 0.2~1.0 mg/dL. The selectivity of bilirubin versus biliverdin was 2.13. Additionally, the RTIL-MIP electrode could distinguish bilirubin in the presence of serum. Therefore, the results confirm the feasibility of the RTIL-MIP electrode for the detection of bilirubin in serum.

Keywords: bilirubin, molecularly imprinted polymer (MIP), room-temperature ionic liquid (RTIL)

## Abstract

Boron nitride (BN(h)) with a hexagonal close-packed structure has excellent electrical insulation and thermal conductivity. Due to the fact that the plane between the layers is only bounded by Van der Waals forces, it can slide against each other easily as it sustained a resistant force, thus it was often used as a solid lubricant in anti-wear areas. In this study, the submicron BN(h) particles were co-deposited with Ni–P matrix onto iron substrates that by electroless technology. After plating, the Ni–P/BN(h) composite coatings were heat-treated for 1 h at 200°C, 300°C, 400°C, 500°C, and 600°C, respectively. The wear and corrosion resistance of the heat-treated composite coatings were measured. Moreover, X-ray diffraction (XRD) analysis and scanning electron microscopy (SEM) were used to characterize the coatings. The corrosion behavior of the Ni–P and Ni–P/BN(h) coated specimen were evaluated through polarization curves and electrochemical impedance spectroscopy (EIS) in 3.5 wt.% NaCl aqueous solution at the room temperature. Results show that Ni–P/BN(h) composite coatings heat-treated at about 400°C had the maximum hardness, good wear resistance, and corrosion resistance had been improved after heat-treated.[1-3]

# Characterization of the Cr-C-Si<sub>3</sub>N<sub>4</sub> Composite Coatings Electroplated from a Trivalent Chromium Bath

Chia Wen Liao, Kung Hsu Hou, Ming Der Ger  
*Chung-Cheng Institute of Technology, National Defense University*  
33551 Taoyuan County, Taiwan  
celinek8888@gmail.com

Electroplated chromium coatings have been widely used in the automotive and manufacture industries. Due to it with high hardness, shiny appearances, excellent wear resistance and corrosion resistance. The chromium alloys can be obtained from trivalent or hexavalent chromium baths by an electroplating process. However, a conventional Cr(VI) manufacturing process is considered to be a significant problem due to the serious health and environmental hazards. Compared with Cr(VI) plating process, the manufacturing process of Cr(III) has numerous environmental, health and technical advantages. Thus, Cr(III) plating is worth studying, because they are considered to be suitable technology to replace conventional Cr(VI) plating while maintaining the excellent characteristics of chromium plating for certain applications. However, the brittleness of Cr(III) materials limit its scope of application. Many investigations have revealed that the second phase particles are commonly introduced into the materials to enhance its physical, chemical or mechanical properties, such as WC, Al<sub>2</sub>O<sub>3</sub>, CeO<sub>2</sub>, SiO<sub>2</sub>, TiO<sub>2</sub>, SiC and Si<sub>3</sub>N<sub>4</sub>. Therefore, in this study, we suggest using of Si<sub>3</sub>N<sub>4</sub> particles because Si<sub>3</sub>N<sub>4</sub> exhibits excellent friction reducing and wear resisting capability and there are no reports about Cr-C-Si<sub>3</sub>N<sub>4</sub> composite coatings produced by the electrodeposition in a trivalent chromium plating bath.

In the present work, Cr-C-Si<sub>3</sub>N<sub>4</sub> composite coatings were obtained by electroplating under DC conditions from a trivalent chromium bath containing suspended Si<sub>3</sub>N<sub>4</sub> particles. The plating parameters are including Si<sub>3</sub>N<sub>4</sub> concentration in the plating bath and current density. The results of the coating's properties such as that the microstructure, the corrosion resistance, the micro-hardness and the wear resistance were investigated. The surface and cross-sectional micrograph (as shown in Fig. 1) indicates that Si<sub>3</sub>N<sub>4</sub> particles (dark points) are dispersed uniformly within the coatings. The volume percentage content of Si<sub>3</sub>N<sub>4</sub> particles within Cr-C-Si<sub>3</sub>N<sub>4</sub> coatings is about 17.4 vol.%. The surface of Cr-C coatings has a granular morphology and a fine granular morphology exists in Cr-C-Si<sub>3</sub>N<sub>4</sub> composite coatings. It is found that Si<sub>3</sub>N<sub>4</sub> particles can refine grains. Owing to the introduction of Si<sub>3</sub>N<sub>4</sub> particles, the corrosion resistance of the coatings is improved. The hardness of Cr-C-Si<sub>3</sub>N<sub>4</sub> coatings enhances up to 950 Hv, it's higher than 820 Hv of the Cr-C coating's hardness. Wear test results show that Cr-C-Si<sub>3</sub>N<sub>4</sub> coatings have the better wear resistance than Cr-C coatings. This is attributed to the dispersive strengthen effects of Si<sub>3</sub>N<sub>4</sub> result in promoting the composite coatings material strength.

Fig. 1. The microstructure surface morphologies (back scattering model) show that of (a) plane view, and (b) cross-sectional view of the Cr-C-17.4 vol.% Si<sub>3</sub>N<sub>4</sub> composite coating.

# Electrostatic Field-Assisted Direct Potentiostatic and Pulse-Potential Electrodeposition of Prussian Blue Films

Cheng-Lan Lin, Kuen-Yi Ding

*Department of Chemical and Materials Engineering, Tamkang University  
No. 151, Yingzhuan Rd., Tamshui Dist., New Taipei City 25137, Taiwan  
cclin@mail.tku.edu.tw*

Micropatterned functional material thin films have been extensively used in many applications such as energy conversion and storages, fuel cells, photocatalysis, micro-electronics and sensors. Methods of photolithography, micro-contact printing or inkjet printing have been employed to prepare these micropatterned thin films. These procedures usually consist of multiple surface treatment steps. It is envisaged that a micropattern fabrication procedure with fewer surface modification steps would increase its efficiency and reduce cost. In this study, a new method that directly creates a micropatterned thin film on an ITO/PET conducting plastic substrate by electrostatic-assisted electrodeposition is proposed and demonstrated. A micropatterned electrostatic film (mESF), which composed of patterned polyacrylate bumps array on a polyethylene substrate, is firstly attached onto the conductive side of an ITO/PET substrate. Upon the removal of the mESF, a patterned electrostatic field is exhibited on the ITO surface by contact electrification. Micropatterned Prussian blue (PB) thin film then can be directly formed on the surface by potentiostatic or pulse potential electrodeposition under the influence of the electrostatic field. Effects of the electrodeposition parameters on the morphology of the resulted micropatterned PB films are investigated. Possible mechanism of the electrostatic-assisted electrodeposition method is proposed. This method might find its potential applications in preparing micropatterned function material films on conducting substrates.

Figure 1 Optical microscope and scanning electron microscope images of a typical micropatterned PB film prepared by electrostatic field-assisted electrodeposition.

# Copper Coatings for Used Nuclear Fuel Containers: Corrosion Testing

Peter Keech<sup>1</sup>, Sridhar Ramamurthy<sup>2</sup>, Rachel Partovi-Nia<sup>2</sup>, Jian Chen<sup>2</sup>, Becky Jacklin<sup>2</sup>, David Shoesmith<sup>2</sup>

<sup>2</sup>Surface Science Western, Western University, 999 Collip Cir. London, ON, N6G 0J3

pkeech@nwmo.ca

The use of copper as a barrier against corrosion in deep geological repositories (DGRs) for used fuel containers (UFCs) has been explored in Europe, Asia and Canada for many decades, as metallic copper provides thermodynamic stability against anoxic corrosion. Extensive review of corrosion data reveals that damage will be limited to nanometres per year or less, or fewer than 1.3 mm in one million years<sup>1</sup>. In recent years, Canada's Nuclear Waste Management Organization (NWMO) has been developing methods for depositing thin copper coatings directly onto steel-based UFC materials that provide suitable strength to withstand geological processes for many years. The result is the NWMO Mark II UFC, shown in Figure 1, both as a schematic and as a fabricated prototype. This container offers many potential manufacturing and handling advantages, owing to its modest size and low weight; the container depicted is just over 2 m long and < 5 t fully loaded, and compares favourably to a loaded KBS-3 container (> 4 m long and > 25 t)<sup>2</sup>.

**Figure 1: NWMO Mark II Used Fuel Container (a) Schematic and (b) Prototype**

Electrodeposition and cold spray have been explored for coatings, with the former proving to be superior for pre-fabrication (i.e. empty containers/lids), while the latter offers advantages for completing the coating over the closure zone, following weld sealing of a loaded container. As the corrosion barrier, it is necessary for the copper coatings to perform as well (or better) than wrought copper materials, for which a large copper corrosion database exists. Corrosion testing of the coating materials has been extensive, consisting of long term exposures to oxic and anoxic conditions as well as accelerated electrochemical measurements. Coating materials have demonstrated corrosion performance that is similar to that of the wrought copper reference materials, with the exception of the accelerated testing in which there are subtle differences among the materials with respect to surface texturing, observed via post-experiment surface analysis. However, throughout the experiments, there is consistency among corrosion potential measurements for the coating and wrought materials, as these fall within a few mV of each other under different conditions such as oxic and anoxic exposures and in accelerated electrochemical measurements. An example is presented in Figure 2, for an experiment that was initially oxic and then anoxic. Results from all of these experiments and the supporting surface analysis, will be described in this paper.

**Figure 2: Corrosion Potential versus time plot for the samples exposed initially under O<sub>2</sub> purging, then followed by Ar-purging**

Supported nanostructured electroactive materials can be fabricated by multiple methods. However, electrodeposition offers several advantages since the nanostructures are grown on the final support. To produce highly electroactive nanostructures, the electrochemical nucleation and growth mechanisms on the nanoscale need to be understood. In this context, Deep Eutectic Solvents (DESs) have generated great enthusiasm as a new generation of non-aqueous electrolytes [1]. They offer several advantages, such as high stability at high temperatures and broad electrochemical windows. Likewise, DESs are easier to prepare, less toxic and much cheaper than room temperature ionic liquids (RTILs) [1]. Nanoscale electrodeposition from DESs is relatively new but has already been proven effective to deposit metallic nanostructures. Moreover, DESs are especially interesting because of their ability to stabilize nanoclusters [2] and to facilitate nanoparticle self-assembly. Hence, nanostructures that would not be attainable with traditional aqueous electrolytes could potentially be generated.

During the last years we have developed an approach based on using carbon coated TEM grids as electrodes. This way, by combining atomic-scale TEM characterization with electron tomography and electrochemical measurements, we have found evidence that has led us to suggest an electrochemical aggregative growth mechanism [3]. It includes nanocluster self-limiting growth, surface diffusion, aggregation and coalescence as important electrochemical growth mechanisms [4].

In this presentation, we use this approach to evaluate the electrodeposition of nickel nanostructures from a 1:2 choline chloride – urea DES. Electrochemical techniques, such as cyclic voltammetry and chronoamperometry, are employed to understand the electrochemical reactions occurring during nickel deposition. Special attention is given to the interaction between the solvent and the electrodeposited nickel phase. The influence of temperature, electrolyte composition and applied potential waveforms on the early stages of nucleation and growth was evaluated. FESEM, XPS and TEM characterization is combined with electrochemical data to gain understanding on these phenomena and to highlight possible benefits of the use of DESs as alternative electrolytes.

The outcome of this investigation shows that, within a wide range of deposition parameters, a large population of small nickel nanostructures (< 20-30 nm) can be obtained. Interestingly, these nanostructures are formed by aggregated nanoclusters of few nanometers in diameter [5]. This indicates a self-limiting growth mechanism, which may be caused by the interaction of the DES with the growing nickel phase. These results show that metal electrodeposition from DESs can be of great interest to produce nanostructures with electrocatalytic properties.

CuMn alloyed film is of particular interest for surface corrosion protection and diffusion barrier in semiconductor Cu damascene processing. In this work, we carry out the electrodeposition of CuMn thin film using a nonaqueous electrolyte. Precursors including  $C_{10}H_{14}CuO_4$  and  $Mn(C_5H_7O_2)_2$  are dissolved in solvents of  $C_2H_4(OH)_2$  and  $CH_3COOH$ , followed by galvanostatic deposition onto Pt-coated ITO substrates. Parameters including precursor concentrations (their molar ratios), plating temperature, plating time, and electrode distance are deliberately varied to identify the optimized processing conditions for uniform CuMn deposit. Material characterization including scanning electron microscope, energy dispersive X-ray spectroscopy, X-ray diffraction spectrometer, and X-ray photoelectron spectroscopy are employed to investigate the composition, surface uniformity, phase, and crystallinity of the CuMn film. In addition, X-ray absorption spectroscopy is involved to understand the reduction process of Cu and Mn cations in the plating bath and the atomic distribution of the Cu and Mn in the deposit. Electrochemical parameters are carefully explored to explain the deposition mechanism and its effect on the resulting compositional inhomogeneity and overall makeup of the CuMn film.

Semiconductors of interest in the solar energy conversion field were prepared by electrodeposition. In particular, we used the E-ALD (Electrochemical Atomic Layer Deposition) [1] method to build a p-n junction. The obtained ultra-thin films were characterized through SXRD (Surface X-Ray Diffraction), with the aim of performing a structural characterization of the grown films.

E-ALD is a layer-by-layer electrodeposition based on the alternate Under Potential Deposition (UPD) of atomic layers of the elements constituting a compound. The starting point was the deposition of the p layer, (Cu-Zn-S), prepared alternating the UPD of the binary sulfides, CuS and ZnS. After the optimization of the deposition condition of the p film [2-4], the electrochemistry behavior of the Cd solution on the substrate covered by the p films has been studied, in order to optimize the deposition of the n film (CdS). To determine the UPD of Cd, voltammetric studies of the Cd solution on the Ag electrode covered by the p films have been done. In these condition the window of electroinactivity of the new substrate is small, thus it is possible to observe the UPD and the bulk reduction peak of Cd, but it is impossible determine the amount of Cd deposited by linear stripping voltammetric studies, because the redissolution potentials of Cd and Cu-Zn are overlapped. In order to verify the effective deposition of Cd and the UPD nature of the deposition, some different samples have been prepared and then characterized by X-Ray Photoelectron Spectroscopy (XPS) and SEM microscopy and microanalysis. The samples have been growth layer-by-layer, or by EC-ALD, or checking the amount of Cd deposited integrating the charge deposited during time with an appropriate software, in a way to assure the deposition of a single monolayer.

XPS results show the presence of cadmium as sulfides in all the samples and in comparable amount, thus verifying the UPD nature of the cathodic peak at less negative potential.

In situ SXRD measurements performed at ESRF (Grenoble), allowed to investigate the growth mechanism of Cu-Zn-S thin films (the p layer). The growth of the film was monitored by following the evolution of the Bragg peaks. Analysis of these data are still in progress but the samples show crystallinity, proposing E-ALD as method to grow structurally ordered thin films.

# Using Copolymers as Suppressors in a Copper Plating Bath for Through-Hole Filling

Shih-I Wen, and Wei-Ping Dow\*

*Department of Chemical Engineering, National Chung Hsing University  
205 Kou-Kuang Rd., Taichung, 40227 Taiwan, R.O.C.  
dowwp@dragon.nchu.edu.tw*

Recently, a copper electroplating technique, namely butterfly technique (BFT) <sup>[1]</sup>, was developed to achieve a void-free filling of a through hole (TH) of a printed circuit board (PCB). However, the BFT for TH filling caused an issue of thick copper layer on the PCB surface, which increases the process cost due to a requirement of post copper etching process. Literature has mentioned that copolymers have strong suppression on copper electroplating than poly(ethylene glycol) (PEG). The strong suppressor can minimize surface copper thickness to achieve excellent filling performance. In this work, we employ a copper filling formula to perform the TH filling. Several copolymers were employed as suppressors to replace PEG. The result shows that the surface copper thickness is decreased by using the copolymer. It can not only enhance the copper filling performance but also increase plating efficiency.

# Electromagnetic Shielding Polyamide Fabrics prepared by Electroless Ni Plating with Chitosan-Nickel Complexes Activation

Yaping Zhao, Hong Zhao, Caihong Liu, Bingzheng Song, Zaisheng Cai  
College of Chemistry, Chemical Engineering & Biotechnology, Donghua University, Shanghai, China  
E-mail address: [zhaoyaping@dhu.edu.cn](mailto:zhaoyaping@dhu.edu.cn)

Electroless plating has been used for modifying the surface of textiles and imparting potential for textile products with functional and decorative applications [1]. Electroless nickel plating has been widely applied due to its deposit properties, such as good electrical and magnetic properties, excellent corrosion and wear resistance as well as deposit uniformity, etc [2]. Noble metal palladium is usually employed as the catalyst sites in the conventional activation processes to initiate the electroless plating, in which the cost of Pd and its compounds are very expensive. It is important to develop a cost effective activation method to replace Pd activating solution [3]. In this work, electromagnetic shielding polyamide fabrics are prepared using chitosan-nickel (CS-Ni) complexes as activators and sodium borohydride as reductant during the pretreatment process, followed by electroless nickel plating. CS-Ni complexes are prepared by the complexing adsorption between  $\text{Ni}^{2+}$  and CS which pre-coated on fabrics. A hydrazine reduction chemical plating nickel reaction system with ammonia as complexing agent is utilized to obtain a pure Ni coating on textiles. The surface morphology, microstructure and composition of the nickel-plated fabrics are analyzed by using emission scanning electron microscopy (FESEM) and energy dispersive spectroscopy (EDS), X-ray diffraction (XRD) and thermogravimetric analysis (TG). The prepared polyamide fabrics has a saturation magnetization of 330 emu/g and a excellent electromagnetic shielding effectiveness (SE) of 50-80 dB during 300kHz~3000MHz. This approach reveals a promising potential to fabricate electromagnetic shielding materials, in which nickel salt is as activator instead of metallic palladium to realize the palladium-free activation.

**Fig.1 FESEM images of the obtained fabrics (a) after activation and (b) after electroless plating; (c) EDS picture and (d) SE curve of the nickel-plated polyamide fabric**

As the climate change continues, harvesting solar energy and solar energy conversion by means of photovoltaic materials in particular are receiving significant scientific interest. In this work, a systematic investigation was performed to study the variation of voltammetric peaks during electrodeposition of copper, indium, gallium, and selenium on molybdenum electrode. The objective of the work was to methodically understand the variation of different oxidation-reduction peaks from unary to quaternary composition so that the comprehensive understanding on their peaks can be arrived. The electrodeposits were then characterized by X-ray diffraction, scanning electron microscopy/energy-dispersive spectroscopy. The results are expected to be helpful to get new insight, for example, on the variation of different voltammetric peaks originating from molybdenum as well as indium.

# Contact Resistance of Thin Gold Overlay on Cu-Sn Alloy Electrodeposits with Various Compositions

Toshihiro Nakamura, Takayo Yamamoto, Tomio Nagayama  
Kyoto Municipal Institute of Industrial Technology and Culture  
91Chudoji Awata-cho, Shimogyo-ku, Kyoto 600-8815, Japan  
86nakat@tc-kyoto.or.jp

Electrodeposition is a key technology for thin-layer process in the fields of surface finishing for electronic materials. High connector reliability can be achieved by using a gold plating on the electrical contacts. Gold, when applied to the contact interface, has the capability of providing a stable and low contact resistance over the operating life of most applications, because gold is a noble metal and does not form corrosion product films. Thin gold coatings can establish a stable and low contact resistance but decreasing the thickness of a gold plating tends to increase the porosity which enlarges the contacts' vulnerability to pore corrosion. Pore corrosion can occur at the under layer plate and exposed base metal locations where pores in the gold coincide with pores in the under layer plate. Accordingly, the durability of the thin gold plated products depends on quality of under layer greatly. Typically, nickel plating is widely used under layer for gold. However, nickel is classified as a skin sensitizer and as a material suspected as being able to cause cancer via inhalation. The Control of Substances Hazardous to Health (CoSHH, U.K.) Regulations 2002 require that skin exposure to nickel and nickel salts is prevented or adequately controlled at work. In contrast, we recently demonstrated that silver white Cu-Sn alloy electrodeposits(40-55mass%Sn), called "speculum alloy," which has been investigated as an promising alternative to an allergenic nickel coating, can be obtained from environmentally-friendly cyanide-free Sulfosuccinate Bath[1]. In this study, the contact resistance of the thin gold(Au0.1 $\mu$ m) overlay on Cu-Sn alloy electrodeposits containing 40 to 71mass% Sn were examined by the aging test (salt spray test) compared with bright nickel coating.

The contact resistance of thin gold overlay on the bright nickel coating began to increase, after only eight hours, much more quickly than that of Cu-Sn alloy deposits. On the other hand, Cu-Sn alloy deposits as an under layer restrained degradation of contact resistance, in particular, thin gold overlay on the Cu-Sn alloy deposits containing 40 to 55 mass% Sn, called "speculum alloy," maintained a lower contact resistance during the salt spray test for prolonged periods (Fig. 1). Contact resistance durability of the specimens using Sn rich Cu-Sn alloy deposits with Sn contents of 61 mass% or above tended to reduce with increasing Sn content. Gold thickness can be reduced by using the Cu-Sn alloy deposits as an undercoat.

Fig.1. Effect of salt spray test on contact resistance of thin gold(Au0.1 $\mu$ m) overlay on Cu-Sn alloy electrodeposits with various compositions or Bright Ni

## 1. Introduction

Metallic lusters exhibited by gold, silver, and copper have designability and functionality for many applications such as automotive coatings, roof coatings, printing inks, cosmetics, and plastic materials for protective and decorative purposes. For such applications, metal effect pigments or flakes of metals have been used and produced by grinding metal granules in a ball mill. After filtration, the pigment flakes are supplied in the form of a paste with organic compounds. By applying the paste, the metal flakes cause a lustrous properties in the films since they are oriented parallel to the substrate plate after drying. However, these metal flakes in the paint have some drawbacks such as sedimentation, corrosion, and heavy weight. In order to overcome these drawbacks, the organic materials for use in the gold-like coatings have been investigated. Recently, our group reported the first chemical synthesis of organic materials capable of forming air-stable gold-like coatings.<sup>1, 2)</sup> Following this chemical approaches, we also successfully produced lustrous metal-like films using an electrochemical technique. In this study, we report the preliminary study on their electrochemical preparation method and their spectroscopic characterization.

## 2. Experimental

3-Methoxythiophene (MeOT), lithium perchlorate (anhydrous) ( $\text{LiClO}_4$ ), sodium dodecyl sulfate (SDS), and distilled water were purchased from Wako Pure Chemical Industries, Ltd and used as supplied. 1-butanol (>99%) was purchased from Kanto Chemical Co., Inc. and used as supplied. Films were obtained by electro-oxidation of 0.1 M MeOT dissolved in mixed solution ( $\text{H}_2\text{O}$ :1-butanol = 96:4 vol%) containing 0.1 M  $\text{LiClO}_4$  and 0.1 M SDS at room temperature using cyclic voltammetry. The working ITO electrode and the counter Pt plate were immersed in the main compartment of the two-compartment type electrolysis cell. The auxiliary compartment, which is separated from the main one by a sintered glass frit, had an immersed KCl agar bridge connected to the reference saturated calomel electrode (SCE). The produced films were characterized by UV-vis reflection spectra using a spectrophotometer (U-3000, Hitachi) with an integrating sphere, observation using an optical microscope (VHX-2000, Keyence), and wide-angle X-ray diffraction measurements (XRD) using a diffractometer (Rigaku SmartLab) equipped with a  $\text{CuK}\alpha$  ( $\lambda = 1.54 \text{ \AA}$ ) source.

## 3. Results and Discussion

Fig. 1 shows the photograph of a lustrous metal-like film produced by cyclic voltammetry at a sweep rate of 10 mV/s in the potential range between -0.5 V and 1.3 V (the number of sweep: 11). Fig. 2 shows the reflection spectra of the film (solid line) and a vacuum-evaporated gold film (dashed line). The former spectrum is nearly the same as the latter in shape and a rising wavelength of reflectance, indicating that the recognized color of the film is gold. The XRD measurement of the film exhibited reflections at  $2\theta = 7.96$  and  $26.04^\circ$ . Based on previous reports on the structural analyses of the poly(3-alkylthiophenes), its reflections indicate a well-defined lamellar structure. The peak at  $2\theta = 7.96^\circ$  correspond to first-order and higher order reflections from the lamellar interlayer spacing, and the peak at  $2\theta = 26.04^\circ$  correspond to the stacking distance of the thiophene rings between two molecular chains. This highly ordered structure most likely exhibits the lustrous feature of the film.

Fig. 1 Photograph of the metal-like lustrous film.

## 1. Introduction

In the present study, we demonstrated a polystyrene (PS) and polymethyl methacrylate (PMMA) particles composite nickel coatings for new intelligent self-lubricant film. Phase transition is the transformation of thermodynamic system from one phase to another one by heat transfer. PS and PMMA particles are known to show a glass-liquid phase transition at 100°C and 105°C, respectively. The PS and PMMA particles composite coating films are expected to increase its lubricity drastically by transformed to liquid phase over the glass-liquid phase transition temperature. Certainly, the particles may show good lubricant property in a low temperature. In this study, we investigated the lubricant properties in detail.

## 2. Experimental

PS and PMMA particles were prepared by soap-free emulsion polymerization [1,2]. The PS and PMMA particles of 0.2, 0.6 and 1.0  $\mu\text{m}$  diameter were used throughout. A Watts bath is used as the plating bath. The particles were injected in the Watts bath containing a cationic surfactant, hexadecyl trimethyl ammonium bromide (CTAB). The electroplating under constant current condition was carried out by two electrode system. Copper and nickel sheets were used as the working electrode and counter electrode, respectively. Friction coefficient of the plating film was evaluated by Bowden-Leben type reciprocating friction tester under following measurement conditions; friction load: 10 N, sliding distance: 6 mm, sliding count: 250 times, test temperature: 40, 70 and 100 °C.

## 3. Results and Discussion

SEM images of 0.2  $\mu\text{m}$  polystyrene particle composite nickel coating was shown in Fig. 1. It was confirmed that polystyrene particles are incorporated into the nickel plating film uniformly. The relationship between the friction coefficient and temperature of the plating film was shown in Fig. 2. The friction coefficient of the composite coating films at 100 °C became smaller than that at 40°C and 70°C. In the case of 100 °C, the friction coefficient of 0.2  $\mu\text{m}$  PS particles composite plating film was estimated about 0.11, which was 2.9 times lower than that of a bare nickel plating film.

Fig. 1 SEM images of 0.2  $\mu\text{m}$  polystyrene particle composite nickel coating. (a): surface image, and (b) : cross-section image. The nickel film was electrodeposited at  $-30 \text{ mA cm}^{-2}$  for min.

Fig. 2 Changes in the coefficient of friction by changing temperature of the plating film

Electrodeposition is a commonly used method to fabricate components used in electronic devices [1]. However, formations of defects in the electrodeposited materials are crucial problems when applied in electronic devices, especially when the devices are miniaturized. Co is a commonly used material in electronic devices, such as random-access memory. Eliminating defects in the electrodeposited Co is more critical when demand of higher memory density is needed.

Evolution of H<sub>2</sub> gas and adsorption of the H<sub>2</sub> gas bubbles on surface of the cathode are believed to be one of the major causes of defects formed in the electrodeposited materials [2]. In previous studies, an electrodeposition method with supercritical CO<sub>2</sub> emulsions (SCE) is found to be effective in removing defects formed in the electrodeposited materials [3-5]. H<sub>2</sub> and CO<sub>2</sub> are both non-polar, therefore, desorption of the H<sub>2</sub> gas bubbles can be significantly improved after usage of the CO<sub>2</sub>. However, because of the non-polar property, electrical conductivity and metal salts solubility are both very low in CO<sub>2</sub>. Therefore, surfactants are needed to form an emulsified electrolyte composed of the supercritical CO<sub>2</sub> and the aqueous electrolyte to allow conduction of an electrochemical reaction [3]. In addition, effects of surface smoothening and grain refinement are observed in the electrodeposited Ni [4] and Cu [5] films. However, Co materials fabricated by electrodeposition with SCE (EP-SCE) have not been well studied. In this study, the SCE is applied in electrodeposition of Co. Effects of the SCE in removal of defects, morphology, and crystal structures of the Co films are evaluated.

A two-electrode system and high pressure apparatus for formation of the SCE were used in this study [4]. Co films with a theoretical thickness of about 70 μm when 100% current efficiency is achieved were electrodeposited on pure Cu (99.99%) plates, which is the cathode electrode. Pure Pt (99.99%) plate was used as the anode electrode. Both electrodes have dimensions of 10mm\*20mm\*0.5mm. The Co electrolyte was composed of CoSO<sub>4</sub> · 6H<sub>2</sub>O 300 g/L, CoCl<sub>2</sub> · 6H<sub>2</sub>O 45 g/L and H<sub>3</sub>BO<sub>3</sub> 40 g/L. The deposition temperature was varied from 25 to 40 °C. For formation of the SCE, non-ionic surfactants, polyoxyethylene lauryl ether (C<sub>12</sub>H<sub>25</sub>(OCH<sub>2</sub>)<sub>15</sub>OH)<sub>2</sub>, were used. The pressure for EP-SCE was 15 MPa. Current density was varied from 5.0 to 15.0 A/dm<sup>2</sup>. A scanning electron microscope (SEM) was used to observed surface of the films. X-ray diffraction (XRD) method was used to conduct crystal structural analysis of the Co films.

For the Co films obtained from the electrodeposition at ambient pressure and without the surfactant, hemi-spherical shaped particles were observed by SEM. After adding the surfactants into the bath, morphology of the particles were still hemi-spherical with uniform size, but average diameter of the particles sharply decreased from roughly 12 μm to 6 μm. We suggested the effect is caused by adsorption of the surfactant on surface of the cathode. When EP-SCE at 15 MPa was used, shape of the particles changed. Ridge-like morphology was observed, and growing orientation of the particles was perpendicular to surface of the electrode. In addition, the XRD results showed crystal structure of the Co films was mainly hexagonal close-packed (hcp) structure, and the crystal structure was mainly face-centered cubic structure after application of the EP-SCE.

# Control of Crystal Orientation of Electrodeposited Aluminum Films from Bath Using DMSO<sub>2</sub> as a Solvent

Yuya Ito\*, Nobuaki Watanabe, Ichiro Koiwa

College of Science and Engineering, Kanto Gakuin University

1-50-1, Mutsuurahigashi, Kanazawa-ku, Yokohama-shi, Kanagawa 236-8501, Japan

koiwa@kanto-gakuin.ac.jp

The control of the crystallographic orientation is one of the most important techniques for a semiconductor device process, corrosion process and crystal growth process. Especially for aluminum, the crystallographic orientation has some influence on the initiation and propagation of localized corrosion and oxidation. In this study, we have investigated the effect of deposition potential on the crystal orientation using aluminum chloride and dimethyl sulfone (DMSO<sub>2</sub>) for an organic solvent.

We used two different composition baths, that the mol ratio between dimethyl sulfone and aluminum chloride is 10:3 and 10:5. The electrodeposition performed under nitrogen atmosphere after dehydration process at 150 °C for 30 minutes. The aluminum films have been electroplated for electric potential region from -0.5 V to -3.0 V by using Al/Al<sup>3+</sup> reference electrode. Bath temperature is 150 °C, and substrate is a copper sheet (10 x 10 mm).

Figures 1 and 2 shows scanning electron microscope (SEM) images of the samples. The bright and smooth surface was observed in the samples from the 10:3 bath. In contrast, matt surface and granular crystals were observed in those from those from the 10:5 bath. Figure 3 shows X-ray diffraction patterns of the films. It is found that the crystallographic orientations of the samples were changed accompanied by deposition potential. The intensity of the (200) peak is stronger than that of (111) for the films from 10:3 bath. The peak intensity ratio between (111) and (200) is 2:1 for the bulk materials. These results show that the films are strongly oriented along the (200) plane. On the other hand, the films from 10:5 bath are slightly oriented along the (200) plane.

# Pulse Electroplating of Cu-Mo Alloy Film Using Disodium Molybdate

Sho Kawamura, Nobuaki Watanabe, Ichiro Koiwa

Kanto Gakuin University, Kanazawa-ku, Yokohama-shi, Kanagawa 236-8501, Japan  
m15J6002@kanto-gakuin.ac.jp

Electronic devices are desired to be larger integration, smaller size, higher speed and higher power, resulting in larger thermal generation, recently. Thermal generation from electronic devices such as a light emitting diode (LED) deteriorates reliability and shortens lifetime, also it causes thermomechanical stress, leading to distorting and breaking chips or packages. A substrate for heat radiation is necessary for LED and thermal coefficient value of substrate is desired to be near that about LEDs. There are some previous studies of Mo alloy films, however there is few study of Cu-Mo alloy films. In this paper, we propose a Cu-Mo alloy films, formed by electrochemical technique, as the heat radiation substrate for the LEDs.

Bath composition is following, copper ( $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ ) whose concentration is  $0.13 \text{ mol/dm}^3$ , disodium molybdate ( $\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$ ) whose concentration is  $0.53 \text{ mol/dm}^3$ , and trisodium citrate whose concentration is  $0.91 \text{ mol/dm}^3$ . In addition, pulse plating conditions are as follows, a current density is controlled from 1 to  $100 \text{ mA/cm}^2$ . A duty cycle and frequency are fixed at 0.1 and 1Hz, respectively, and a bath temperature is controlled from 2 to  $60^\circ\text{C}$ . Surface was observed by scanning electron microscope (SEM). The composition of plated film was analyzed by energy dispersive X-ray spectrometry (EDS). An adhesion strength of electroplated Cu-Mo alloy film to a nickel substrate was evaluated by using a universal mechanical strength tester (Romulus, Quad Group Inc, shipped by Phototecnica co.Ltd.)

Figure 1 shows effect of current density on the Mo content in the plated films. The molybdenum content of electroplated Cu-Mo films abruptly increased with increasing current density for the region of current density less than  $10 \text{ mA/cm}^2$ , then the Mo content gradually decreased with increasing current density for the region less than  $50 \text{ mA/cm}^2$ , and it somewhat increased for the higher current density region. Maximum Mo content is 18.3 at % at  $10 \text{ mA/cm}^2$ .

Figure 1 shows three typical scanning electron micrographs of Cu-Mo alloy films plated at  $5.0 \text{ mA/cm}^2$  (a),  $10 \text{ mA/cm}^2$  (b),  $100 \text{ mA/cm}^2$  (c), respectively. Surface morphology of the plated film at  $5.0 \text{ mA/cm}^2$  shows closely packed grain structure and the grain boundaries were clearly observed. On the other hand, that at 10 and  $100 \text{ mA/cm}^2$  show flat surface and finer particles are observed. The differences between two films are mainly caused by Mo content, 6.8 at% and 18.3 at%, 14.3 at %.

Table 1 shows effect of current density on adhesion strength between electroplated Cu-Mo alloy and Ni substrate. The adhesion strength decreased with increasing current density for the region of current density less than  $50 \text{ mA/cm}^2$  and the minimum value of  $7.0 \text{ kg/cm}^2$  was obtained at  $50 \text{ mA/cm}^2$ . However, the maximum adhesion strength,  $106 \text{ kg/cm}^2$ , was obtained at  $100 \text{ mA/cm}^2$ .

This work was partially aided by MEXT-supported Program for the Strategic Research Foundation at Private Universities.

The coexistence of nonmetal particles in metallic matrix improve the mechanical and chemical properties such as wear resistance, self-lubrication, corrosion resistance and metal-polymer adhesion. Dr. S.Oue and his co-workers have reported that Zn-Al<sub>2</sub>O<sub>3</sub> composite films were plated from non-suspended solution by using quaternary ammonium salt<sup>1)</sup>. The zinc matrix with aluminum oxide particles composite films from non-suspended solution containing quaternary ammonium salts were also investigated. The solution contains 520 mol/m<sup>3</sup> ZnSO<sub>4</sub>·7H<sub>2</sub>O and 79 mol/m<sup>3</sup> Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>·14-18H<sub>2</sub>O as metal source. A quaternary ammonium salts of Benzyltrimethyltetradecylammonium chloride dehydrate (BDTAC, Wako Co.,Ltd.) was used in this study.

Fig.1 Transmission electron micrographs of the samples with maximum Al content.

Table 1 Composition of area D in Fig.1.

Element	Weight %	Atomic %
O	4.4	15.7
Al	0.8	17.0
Zn	94.8	82.6

Table 2 Composition of area E in Fig.1

Element	Weight %	Atomic %
O	7.8	20.6
Al	18.6	29.2
S	3.4	4.5
Zn	70.2	45.6

Figure 1 shows micrographs observed by transmission electron microscopy (TEM). Two different deposits were observed, one is needle-shaped deposit and the other is closely packed fine particle area. Magnified photograph shows closely packed fine particle area and fine particles are clearly observed. Table 1 shows result of composition analysis of D area, needle-shaped deposit, in Fig.1. The area is composed of 82.6 at% zinc, 17.0 at% aluminum and 15.7at% oxygen. Table 2 shows result of composition analysis of E area, closely packed fine particle area, in Fig.1. The area is composed of 45.6 at% zinc, 29.2 at% aluminum, 20.6 at% oxygen and 4.5 at% sulfur. The zinc content of area D, needle-shaped deposit, is much higher than that of area E, closely paced fine particle area. On the other hand, the aluminum content of area E is much higher than that of area D. It is concluded based on above results that the needle-shaped deposit is mainly composed of Zn or ZnO, and the fine particle is mainly composed of Al(OH)<sub>3</sub> or Al<sub>2</sub>O<sub>3</sub>. The origin of sulfur is not clear, because there is no sulfur in this plating bath except for sulfur of sulfate. Since the oxygen content in area E is higher than that in area D, it is suggested that the codeposited aluminum increases oxygen content in the films.

According to above results, the aluminum have been deposited from aqueous solution by using the quaternary ammonium salts of Benzyltrimethyltetradecylammonium chloride dehydrate and aluminum is deposited with oxygen and formed the fine particles. Therefore, this method is effective to codeposit aluminum from aqueous solution and to form the composite film from non-suspended solution. The co-deposited particles is too fine to detected X-ray diffraction and crystallinity is too low to detected by electron beam diffraction.

Graphene is two-dimensional carbon sheet with honeycomb structure, and has attracted attention for its excellent properties. Thus, it is expected that graphene is promising material in a wide range of applications, including electronics, spintronics, optoelectronics, sensors, batteries and supercapacitors. For applications of graphene, various techniques for synthesis of graphene have been developed, such as the graphitization of silicon carbide surfaces and catalytic chemical vapor deposition (CVD) on metals. Most of the synthesis methods require high-temperature condition above 1000 °C.

Recently, the method for synthesis of single-walled carbon nanotubes (SWCNTs) by the electrochemical reaction was reported<sup>2</sup>. In this method, SWCNTs are deposited by the electrochemical decomposition of acetic acid at room temperature. This reaction produces a carboxylate anion, an aldehyde, an alcohol, and a hydrocarbon. During cathodic reaction, the reduction process from acetic acid to ethane will produce  $C_2H_5$  radicals, and the carbon material is synthesized by partial dehydrogenation and recombination of each radicals. This method has an advantage in synthesis of carbon materials under mild temperature condition by the assistance of electrochemical reaction. However, the method of synthesis graphene by electrochemical reaction has never been reported before.

In this study, we report the novel synthesis route for mono-layer graphene using hydrothermal electrolysis. Hydrothermal electrolysis is the electrolysis method combined with hydrothermal reaction. Graphene sheet was produced over the surface of Pt substrate as a working electrode by applying a small negative potential (-3.5 V) against Pt counter electrode in an aqueous solution of carboxylic acid (formic acid, acetic acid, propionic acid) as a carbon source under sub-critical condition (300 °C, 10 MPa).

Figure 1 shows a scanning electron microscope (SEM) image of the Pt substrate after hydrothermal electrolysis in an aqueous solution of acetic acid. From SEM image as shown in Figure 1, we observed the wrinkles in the carbon sheet, which were independent of location of grain boundary. It is confirmed that the carbon sheet material is deposited by electrochemical reaction under sub-critical condition. Figure 2 shows Raman spectra of the carbon sheet material on the Pt substrate. G ( $1580\text{ cm}^{-1}$ ) and 2D ( $2690\text{ cm}^{-1}$ ) bands due to graphene formation were observed. It is known that intensity of G band ( $I_G$ ) is weaker than that of 2D band ( $I_{2D}$ ) in the Raman spectra of mono-layer graphene. From Raman spectra as shown in Figure 2, we concluded that carbon sheet material on the Pt substrate contains mono-layer graphene. In contrast, only amorphous carbon is deposited by the electrochemical decomposition of acetic acid at room temperature. It is supposed that the growth of high crystalline graphene under hydrothermal condition will result from etching of amorphous carbon due to the oxidation effect of sub-critical water.

Besides, graphene was synthesized by hydrothermal electrolysis using formic or acetic acid as a carbon source, whereas small amount of amorphous carbon was deposited using propionic acid. It is generally known that  $CH_3$  and  $C_2H_5$  radicals are more stable than  $C_3H_7$  radical. Therefore, it is supposed that the growth of graphene using formic or acetic acid is caused by stability of each hydrocarbon radicals.

Cuprous oxide (Cu<sub>2</sub>O) is known as an intrinsic p-type semiconductor with 2.1 eV bandgap, and has attracted increasing attention as a solar cell material. The electrodeposition of Cu<sub>2</sub>O from basic (*i.e.* alkaline) aqueous baths containing copper(II) salt and lactate ( $L = C_3H_5O_3^-$ ) as complex former was first reported by Rakhshani and co-workers [1] and further developed by the groups of Switzer [2], Izaki and Shinagawa [3]. Copper complex(es) dissolved in the basic lactate baths, however, still remains undetermined. A pH speciation diagram for the Cu(II)-lactate system calculated using formation constants of  $CuL^+$ ,  $CuL_2$ , and  $CuL_3^-$ , tabulated in ref. [4], indicates that the baths lead to the formation of  $Cu(OH)_2$  precipitate at pH > 8, whereas the baths in the basic region retain their clearness, while their color changes to dark blue (Fig. 1a). Figure 1c shows a set of UV-vis absorption spectra for 0.4 M  $Cu(CH_3COO)_2 - 3.0$  M lactic acid (HL) baths with various pH values adjusted by NaOH. Beyond pH 6, a blue shift and concomitant decrease in absorbance were observed, implying the formation of chelate complex(es) to increase the splitting of *d*-orbital of copper. Given that the lactate ion(s) chelates  $Cu^{2+}$  ion, the maximum ligand-to-metal ratio should be 2 like  $CuL_2$ , since a Jahn-Teller  $d^9$   $Cu^{2+}$  ion has a tendency to form a square-planar complex. If this is the case, the presence of  $CuL_3^-$  is questionable. In more basic pH region, Panzer *et al.* tentatively supposed a basic dimer complex [5], while Herranen *et al.* claimed the formation of  $H_2L^{2-}$  ions ( $= C_3H_4O_3^{2-}$ ) with the deprotonated  $\alpha$ -hydroxyl-group, yielding  $Cu(H_2L)_2^{2-}$  and  $Cu(H_2L)_2(OH)^{3-}$  [6]. Figure 1b shows a titration curve acquired by titrating 50 mL of 0.4 M  $Cu(ClO_4)_2 - 3.0$  M lactic acid solution with 9.27 M NaOH; here, a curve calculated assuming the above three complexes  $CuL^+$ ,  $CuL_2$ , and  $CuL_3^-$  [4] is also shown. The most notable point is that the final equivalence point (C) for the experimental curve is found about halfway between calculated equivalence points for (A)  $HL + OH^- \rightarrow L^- + H_2O$  and (B)  $Cu(II) + 2OH^- \rightarrow Cu(OH)_2$ , suggesting the final Cu(II)-lactate complex has a formula  $Cu_xL_y(OH)_x^{(y-x)-}$  without  $H_2L^{2-}$  species; the most likely candidate is  $CuL_2(OH)^-$ .

# Mechanical properties of electrodeposited Fe-Ni alloys in the Invar composition range

Tomio Nagayama, Takayo Yamamoto, Toshihiro Nakamura  
Kyoto municipal institute of industrial technology and culture

nagayama@tc-kyoto.or.jp

Invar Fe-Ni alloys with Ni contents around 36 mass% have lower coefficients of thermal expansion (CTEs) near room temperature than those of pure Fe and Ni. Thus, MEMS devices required to have dimensional thermal stability are expected to be provided by Invar Fe-Ni alloy electrodeposition, which can allow shape refinement and strengthening of those devices. We have already produced electrodeposited Fe-Ni alloys with Ni contents in the Invar composition range (36 to 40 mass% Ni) as free-standing films from a plating bath containing saccharin as a strength reducer [1, 2]. It was also reported that as-deposited Invar Fe-Ni alloys had larger CTEs than those of as-cast Invar alloys, moreover, heat treatment at 400 °C or above was necessary to stabilize CTEs of the electrodeposited Invar alloys to those of as-cast Invar alloys [1, 2]. Therefore, it is possible to anticipate strength degradation due to grain coarsening. Additionally, it is also concerned that embrittlement [3] occurs by grain boundary segregation of sulfur originated from saccharin after the heat treatment. In this study, the influences of heat treatment on mechanical properties of the electrodeposited Invar Fe-Ni alloys were examined by tensile testing.

The Invar Fe-Ni alloy electrodeposition carried out on a stainless steel substrate using sulfate / chloride electrolytes with additives at 40 mA / cm<sup>2</sup>. Bath compositions [1] were as follows: FeSO<sub>4</sub> (0.3 to 0.35 mol / L), NiSO<sub>4</sub> (0.95 mol / L), NiCl<sub>2</sub> (0.17 mol / L), boric acid (0.49 mol / L), sodium saccharin (0.008 mol / L) and malonic acid (0.05 mol / L). The bath temperature was maintained at 50 °C and the bath pH was adjusted to pH 2.3. Pure Fe and Ni sheets were used as anodes. Electrodeposited Fe-Ni alloys with Ni contents of 36, 38 and 40 mass% as free-standing films were obtained by varying Fe ion concentration in the plating baths. Dumbbell type specimens with thickness of about 100µm for tensile testing were prepared by an etching method. Figure 1 shows the effects of heat treatment temperature on CTE (30 to 100 °C), ultimate tensile strength (UTS), elongation (δ) and hardness of the Fe-Ni alloy specimens. The CTEs of the as-deposited Invar Fe-Ni alloy films were 8 to 10 ppm / °C which were larger than those of as-cast Invar Fe-Ni alloys. After 400 °C heat treatment, the CTEs drastically dropped to 4 to 5 ppm / °C, and the CTEs reached comparable values to those of as-cast Invar Fe-Ni alloys by annealing at 500 °C or above. Plastic deformation was observed for all specimens on tensile testing. UTS and hardness of the as-deposited Invar alloy films exhibited around 700 MPa and 250HV, respectively, which were higher than those of conventional Invar alloys having UTS and hardness of about 500 MPa and 150HV, respectively. The higher UTS and hardness values were maintained up to 500 °C. By annealing at 600 °C, UTS and the hardness sharply decreased and exhibited comparable values to those of as-cast Invar alloys. Elongation was almost inverse proportional to strength without drastic δ devaluation (i.e. δ < 1 %) which was reported for electrodeposited Ni and Fe-Ni alloys with Ni contents of 60 mass% or above containing sulfur with heat treatment at 400 °C or above [3]. The electrodeposited Invar alloys contained sulfur of about 0.02 mass%; nevertheless, there was no severe embrittlement after 300 to 600 °C heat treatment. Sulfur in the electrodeposits with heat treatment existed as not a filmy sulfide at grain boundary which causes grain boundary embrittlement, but a granular Fe-Ni-S compound in the Fe-Ni alloy matrix.

# One-step Synthesis of Porous BiOBr Film From Bi Plate Via Electrochemical Method

Caimei Fan\*, Yingyuan Hu, Rui Li, Xiaoming Mao

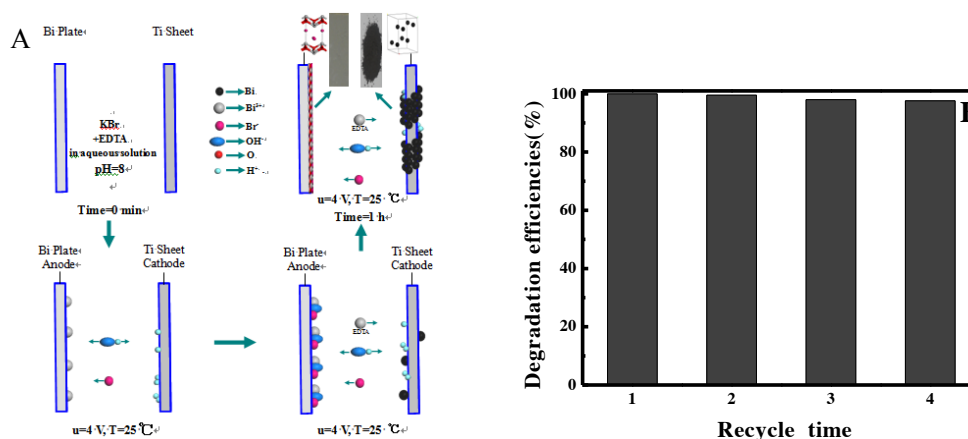

College of Chemistry and Chemical Engineering, Taiyuan University of Technology, Taiyuan, Shanxi, PR China

[fancm@163.com](mailto:fancm@163.com)

With the industrialization and urbanization increasing, the environmental problem and the energy crisis have become a subject of great interest to researchers worldwide. Semiconductor photocatalysis shows great promise in the solution of environmental and energy problems. Owing to the superior electrical, optical, and mechanical properties, photocatalysis has been widely used in many aspects such as air/water purification, solar cell, biological field, gas sensors, and electrochromic devices. Recently, BiOBr has promising practical applications due to its layered tetragonal matlockite structure, indirect transition band gap, and stronger oxidation abilities<sup>[1]</sup>. Most of investigations have focused on the synthesis and characterization of BiOBr nanopowder catalysts. However, limitations associated with separation and recycling difficulties, high aggregation tendency and potential risks for humans hamper their practical application<sup>[2]</sup>. Therefore, to counter these impediments, it is extremely necessary to develop an immobilized BiOBr thin film to achieve excellent photocatalytic activity and extend industrial applications. Moreover, from an environment-friendly perspective, electrophoretic deposition and anodic oxidation should be a desirable strategy to develop BiOBr film and had attracted great research interests<sup>[3-4]</sup>.

In this study, a novel electrochemical approach had been developed to prepare porous BiOBr thin film with bulk Bi plate as anode and Ti sheet as cathode. The experiments were conducted at 4 V for 1 h (25°C) in 100 mL aqueous solution containing 0.5 mol/L KBr and 0.06 mol/L ethylenediamine tetraacetic acid (EDTA). The pH value was adjusted to 8 with 5 mol/L NaOH solution. The schematic preparation process was depicted in **Figure 1A**.

Furthermore, the BiOBr film has also been used in the photodegradation of methyl orange (MO) under ultraviolet light irradiation, and the results indicated that the BiOBr film expressed excellent photocatalytic activities and good chemical stability (**Figure 1B**), facilitating its practical application.

**Figure 1A.** The schematic preparation process for BiOBr films.

**Figure 1B.** Four cycles of photocatalytic process were repeated on one BiOBr film in degrading 50 mL 10 mg/L MO under UV light irradiation.

## Introduction

1. One of the surface hardening treatment of aluminum alloy is iron alloy plating on the surface. It was reported that thin enough iron alloy film deposition would not inhibit its high thermal conductivity of base material-aluminum alloy and would improve the wear resistance of the surface. Especially, Fe-Cr alloy plated coating shows quite high surface hardness and high wear resistance. From this reason such finishing has been adopted as the surface coating for aluminum alloy brake disc of the racing motorcycle for world championship. However, thus plated Fe-Cr alloy coating do not show enough corrosion resistance, so more high corrosion resistance will be desirable for iron alloy plating. In this report newly developed iron based amorphous alloy plating technology has been proposed.
2. Recently especially after Fukushima accident of nuclear power plant caused by Tsunami, from the point of view of environmental aspects and depletion of fossil fuel, hydrogen as a clean energy will be the most attracting secondary energy. Hydrogen production by water electrolysis is beneficial because of the resources are almost inexhaustible and do not emit any harmful substances. Hydrogen has been already widely used as a household fuel cell (Trade name "Ene-Farm") in Japan. Hereinafter the demand for hydrogen storage and supply will spread according to the spread of fuel-cell vehicles. However, for further spread of the hydrogen energy, the cost reduction of hydrogen manufacturing unit will be indispensable. The development of high-performance cathode electrode of water electrolyzer will reduce the cost of hydrogen production equipment and running costs.[1] This research will focus on the application of the Ni, W and P (relatively inexpensive material) amorphous alloy electrode fabricated by use of electrodeposition (relatively inexpensive method) as the electrode for water electrolyzer. For the industrial use of water electrolyzer, sustainable energy e.g. solar energy, wind power and water power will be indispensable, because of the input electric energy cost. Such electric energy produced by sustainable energy will fluctuate. So connecting water electrolyzer must have enough endurance for such a fluctuating electric power. So we have also evaluated the anti-corrosion behavior of thus plated electrode material at open circuit conditions in alkaline aqueous solution.

## Results and Discussions

1. From the experiment Fe-Ni-W amorphous alloy plated film showed higher corrosion resistance comparing to Fe-Cr alloy plated film in 3 % NaCl aqueous solution. It was confirmed the improvement of corrosion resistance according to the increase of W content in the film. The contents of W in the film could be controlled by increasing the concentration of W in the plating bath.
2. The LSV measurement in 30 % KOH aqueous solution (typical alkaline water) implied that amorphous Ni-P coated electrode by use of electrodeposition showed larger exchange current density for hydrogen evolution reaction, and also showed the lower hydrogen overvoltage. On the other hand amorphous Ni-W-P coated electrode showed lower corrosion current density. So amorphous plated alloy will be a desirable candidate for practical use of the electrode for water electrolyzer for sustainable energy.

# Characterization of $\text{AlCl}_3$ /Diglyme Solution for Aluminum Electrodeposition

Kai Nakamura, Atsushi Kitada, Kazuhiro Fukami, Kuniaki Murase  
Department of Materials Science and Engineering, Kyoto University  
Yoshidahonnmachi, Sakyo, Kyoto 606-8501, Japan  
nakamura.kai.54u@st.kyoto-u.ac.jp

Aluminum (Al) has industrial importance because of its lightweight property, natural abundance and corrosion resistance. It is well known that Al metal cannot be electrodeposited from aqueous solutions due to its low redox potential ( $-1.68$  V vs. SHE), while it can be obtained from high temperature molten salts, organic solvents and ionic liquids [1]. However, these electrolytes are highly volatile, highly viscous, and/or expensive for practical use. Glymes have boiling points and flash points over  $100$  °C which give low volatilities at room temperature. Recently we found that Al can be electrodeposited from  $\text{AlCl}_3$ /diglyme solution at room temperature [2]. However, at room temperature the cathodic current density was about  $3 \text{ mA cm}^{-2}$  and more than  $10 \text{ mA cm}^{-2}$  is needed for paractical Al electroplating. Here, we investigated suitable condition for fast electrodeposition in  $\text{AlCl}_3$ /diglyme solution.

All electrochemical experiments were performed at room temperature in an Ar-filled glove box. Al sheets were used as counter and reference electrodes. A Cu sheet was used as working electrode (WE) after being washed with acetone.  $\text{AlCl}_3$  and diglymes were mixed with molar ratio of  $\text{AlCl}_3$ :diglyme = 1:5 ( $1.4 \text{ mol dm}^{-3}$ ) and used as electrolytes. Molar conductivities and viscosities were measured at  $35$ – $70$  °C in an Open Dry Chamber (Daikin) with  $\text{H}_2\text{O} < 40\text{ppm}$ .

Figure 1 shows the cyclic voltammogram (CV) measured for the Cu electrode in the  $\text{AlCl}_3$ /diglyme solution at  $30$ – $70$  °C. The maximum value of current density was observed at  $60$  °C and current density decreased at  $70$  °C. At  $60$  °C cycling efficiency was about 70%. At  $70$  °C it was observed that the electrolyte became gradually brown, or thermally decomposed. It indicates that  $60$  °C is the temperature suitable for fast electrodeposition of Al in  $\text{AlCl}_3$ /diglyme solution. Table 1 shows physical properties of  $\text{AlCl}_3$ /diglyme solution at each temperature. Conductivities increased and viscosities decreased as the temperature is raised. The diglyme solution showed the conductivity of  $3.97$ – $6.48 \text{ mS cm}^{-1}$ . A previous spectroscopic study showed that molecular species ( $\text{AlCl}_3 \cdot \text{diglyme}$ ) and ionic ones of four-Cl coordinated  $\text{AlCl}_4^-$  and six-O/Cl-coordinated  $[\text{AlCl}_2(\text{diglyme})_2]^+$  exist in  $1.7 \text{ mol dm}^{-3}$   $\text{AlCl}_3$ /diglyme solution [3]. Therefore, sufficient conductivity should result from these ionic species. Since  $\text{AlCl}_4^-$  is known to be electrochemically inactive, it is assumed that Al can be electrodeposited by desolvating  $[\text{AlCl}_2(\text{diglyme})_2]^+$ .

Figure 1. CVs measured for  $\text{AlCl}_3$ /diglyme (1:5 by mol) at each temperature. Sweep rate:  $20 \text{ mV s}^{-1}$ .

Table 1. Conductivities and viscosities of  $\text{AlCl}_3$ /diglyme solution measured at  $35$ – $70$  °C.

Temperature	Conductivity ( $\text{mS cm}^{-1}$ )	Viscosity ( $\text{mPa s}$ )
$35$ °C	3.97	2.92
$40$ °C	4.48	2.67
$50$ °C	5.53	2.35
$60$ °C	6.48	2.03

## I. Introduction

Electrodeposition in a magnetic field (B) is different from the deposition mechanism in the absence of B. The reason might be caused by the flow of magnetic convection (Magnetohydrodynamics, MHD). Lorentz force induced by a magnetic field directly influences on the ion species near the electrode surface, while the mechanical stirring does not work there due to the viscosity. Although numerical simulations of MHD have been studied by many researchers [1,2], the relation between Cu electrodeposition and MHD convection is not sufficiently clear. We believe that the understanding of the natural convection and current distribution during the electrodeposition should be important for simulating MHD convection precisely.

We focus the electrical neutrality equation that gives the relation between electric field and concentration in electrolyte and simulate the current density and electric field during Cu electrodeposition [3]. In the present work, two current components by diffusion and electric migration could be separately calculated in the consideration of the diffusion coefficient and mobility of  $\text{Cu}^{2+}$  and  $\text{SO}_4^{2-}$  ions. We will apply the present results of current density distribution for simulating MHD convection.

## II. Results and discussion

Schematic diagram of electrolytic cell is shown in Fig. 1. The current density distributions across L1 and L2 line are calculated under galvanostatic mode ( $20 \text{ A m}^{-2}$ ) for 500 sec. Figure 2 shows Y-direction components of current density at 36 sec (solid line) and 500 sec (dotted line), respectively. Although the value of current density was almost about  $20 \text{ A m}^{-2}$  through whole area, ones at top and bottom area were slightly shifted from the set value (Fig. 2 (a)). This is explained by the gradient of the diffusion layer normal to the electrode. The concentration at the top part is lower than center area, while it is opposite at bottom one. The shift was increased with increasing in the deposition time.

## Abstract:

In this study, the electrochemical behaviors of Zn(II) from different precursors were investigated by various electrochemical techniques using platinum and glassy carbon as the working electrodes in *N*-butyl-*N*-methylpyrrolidinium bis(trifluoromethanesulfonyl)imide room temperature ionic liquid (BMP-TFSI)<sup>1</sup>. The Zn(II) species were introduced into BMP-TFSI by adding ZnCl<sub>2</sub>, (Zn(TFSI)<sub>2</sub>)<sup>2</sup> or directly electrolyzing Zn metal. In the cyclic voltammetric experiments, we found that the reduction of Zn(II) from (Zn(TFSI)<sub>2</sub>) showed a larger over-potential than that from ZnCl<sub>2</sub>. We suppose that the chloride ion (Cl<sup>-</sup>) may compete with the TFSI<sup>-</sup> anion and affect the coordination environment of zinc, leading to a more positive reduction potential of ZnCl<sub>2</sub>. For the Zn(II) species from anodic dissolution of Zn metal, a kinetically stable but thermodynamically unstable Zn(II) species was produced, which gradually transformed to the thermodynamically stable Zn(II) species and finally showed the same electrochemical behavior as that of Zn(II) species from (Zn(TFSI)<sub>2</sub>).

# Recovery of Nanosilver from Si-Wafer Manufacturing Wastes

Tzu-Hsuan Tsai, Yu-Pei Shih

*Department of Materials and Mineral Resources Engineering,  
National Taipei University of Technology, Taipei 10608, Taiwan  
tzhtsai@ntut.edu.tw*

Nanosilver is one of the fastest growing products in the nanotechnology industry, and it is already used in catalysis [1], surface enhanced Raman scattering [2] and many medical applications due to its strong anti-microbial ability [3]. This study successfully used Si-wafer manufacturing wastes to produce nanosilver. Various wastes are formed during Si-wafer manufacturing. Silver ions could be found in the HF etching solutions for forming porous Si. We produced nanosilver using the etching solutions by adding the recovered Si powder from silicon sawing waste. After silver ions reduced to nanosilver and parts of Si oxidized to  $\text{SiO}_2$  in the etching solution, the solid was collected and observed via a scanning electron microscope (Fig. 1), indicating nanosilver is formed on Si powder. In order to purify silver,  $\text{NaOH(aq)}$  was added to dissolve Si or  $\text{SiO}_2$ . As a result, a solution with nanosilver was obtained in the filtrate and observed via a transmission electron microscopy (Fig. 2). The recovery yield of silver from the etching solutions was higher than 99.5%. In addition, most HF could be converted to low toxic  $\text{Na}_2\text{SiF}_6\text{(s)}$ .

Fig. 1 A SEM image of the collected solid after redox reactions of  $\text{Ag}^+$  and Si in etching solutions.

Fig. 2 A TEM image of the obtained solution with nanosilver.

# Fabrication of the three-dimensional micro structure by Fe-Ni alloy electroforming process -Effect of saccharin concentration-

Takayo Yamamoto, Tomio Nagayama, Toshihiro Nakamura  
Kyoto Municipal Institute of Industrial Technology and Culture  
91 Chudoji Awata-cho, Shimogyo-ku, Kyoto-city, Kyoto, 600-8815, Japan  
yamamoto@tc-kyoto.or.jp

Fe-Ni alloys in the content range from 36 to 42 mass% Ni have lower coefficients of thermal expansion (CTEs) near room temperature than those of pure Fe and Ni. Thus, it can be expected to fabricate the next-generation MEMS (Microelectromechanical systems) devices required to have high dimensional stability by a low CTE Fe-Ni alloy electroforming process, which can allow shape refinement and thermal stability in dimension of those devices. However, a strict control in the characteristic composition of the Fe-Ni alloy electrodeposits is difficult because of the anomalous codeposition phenomenon. In addition, a three-dimensional processing with a precious control is required for a fabrication of the MEMS micro structures. Therefore, it is necessary to investigate the effects of the deposition conditions to produce micro structures with uniform composition and shape. In this study, optimum deposition conditions for fabricate a uniform Fe-42 mass% Ni alloy micro structure which can be expected to have a low CTE comparable to that of Si mainly used in MEMS devices by the electroforming process were examined.

The Fe-Ni alloy electroforming was carried out by electrodeposition through negative UV photoresists with 100  $\mu\text{m}$  x 100  $\mu\text{m}$  square dot patterns of 30  $\mu\text{m}$  in height on a stainless steel (SUS 304, 10 mm x 10 mm in area) substrate. The Fe-Ni alloy electrodeposition was operated at 20 mA/cm<sup>2</sup> using sulfate/chloride electrolytes with additives. Bath compositions [1] were as follows: FeSO<sub>4</sub> (0.35 mol/L), NiSO<sub>4</sub> (0.95 mol/L), NiCl<sub>2</sub> (0.17 mol/L), H<sub>3</sub>BO<sub>4</sub> (0.49 mol/L), sodium saccharin (0.008 mol/L) and malonic acid (0.05 mol/L). The bath temperature was 323 K and the bath pH was adjusted to pH 2.0. After the electrodeposition, the resists were removed by sodium hydroxide solution.

Fig. 1a shows a typical 45° tilt view FE-SEM image of the obtained Fe-Ni alloy micro structure. The micro structure having 100  $\mu\text{m}$  x 100  $\mu\text{m}$  square open areas with a structure height of 14.8 $\pm$ 2.4  $\mu\text{m}$  was obtained. The Fe contents at points indicated by cross marks in Fig. 1a were from 56.0 to 59.1 mass% as a result of EPMA analysis. The values of Fe content and height of the Fe-Ni alloy micro structure with Ni content around 42 mass% were widely ranged under this electrolytic condition. From FE-SEM observation of the surface morphology, the micro structure had two different morphologies: spherical and angular grain, as shown Fig. 1b. Subsequently, in order to modify the deposit morphology of the Fe-42 mass% Ni alloy structure, Fe-Ni alloy electrodeposition was operated in the bath with high saccharin concentration of 0.04 mol/L. Fig. 1c shows a typical FE-SEM image of the obtained Fe-Ni alloy micro structure at saccharin concentration of 0.04 mol/L. The Fe contents and the height of the Fe-Ni alloy micro structure were 57.0 $\pm$ 0.1 mass% and 15.8 $\pm$ 1.1  $\mu\text{m}$ , respectively, the variation of the values of Fe content and height was reduced by increasing saccharin concentration. As shown Fig. 1d, the uniform spherical grains were observed on the surface of the micro structure.

From these results, it is found that it is possible to fabricate the uniform Fe-42 mass% Ni micro structure having square open areas which was precisely transcribed from the shapes of the photoresists from the bath with high saccharin concentration.

Light emitting diode (LED) light sources have been widely used in various fields like television display, room lighting, and automotive headlight, due to their high energy-saving capacity, low voltage requirement, small size, long life, etc. Generally, LED electroluminescence components in the package are set on Ag-coated Cu alloy plates as LED lead frame, which is required to provide stable light reflective performance and excellent electrical and thermal conductivity. Since Ag is a noble metal with increasing price of Ag nowadays, it is highly desirable to search a low-cost coating material with high reflectivity and durability to replace the costly Ag film on the lead frame.

This investigation reported various multilayered Sn/Ag-based films on Cu alloys toward high reliable reflective films for LED lead frame. The multilayered Sn/Ag<sub>3</sub>Sn-based films consisted of an Ag-Sn alloy of 20–500 nm thickness covered on a reflowed Sn (denoted as Sn-RF) layer on Cu alloy plates, which can be roughly divided into two categories, i.e., Sn/Ag<sub>3</sub>Sn and Sn/Ag<sub>3</sub>Sn/Ag films, corresponding to the thickness of electrodeposited Ag layer. Fig.1 gives the representative reflective spectra of multilayered Sn/Ag<sub>3</sub>Sn and Sn/Ag<sub>3</sub>Sn/Ag films before (solid lines) and after heating at 373 K for 120 h (dotted lines), comparing to commercial Ag, Sn-RF, and Au films on Cu alloys. The initial reflectivity of as-deposited Sn/Ag<sub>3</sub>Sn films were around 70% (450 nm), which was lower than an Ag film (~90%) but much higher than an Au film (~24%). The multilayered Sn/Ag<sub>3</sub>Sn/Ag films, on the other hand, exhibited a high reflectivity equivalent to a commercial bright Ag film, which can be attributed to the smoother surface inherited from the underlying Sn-RF film on Cu alloys. Noticeably, the reflectivity of multilayered Sn/Ag<sub>3</sub>Sn-based films was stable even after heating at 373 K for 120 h, indicating a good thermal stability.

Moreover, sulfidizing resistance of multilayered Sn/Ag<sub>3</sub>Sn-based films before and after heating was also investigated by accelerated sulfidizing tests with a 2 ml/L (NH<sub>4</sub>)<sub>2</sub>S<sub>x</sub> solution. The microstructures and various characteristics of the Sn/Ag<sub>3</sub>Sn-based films were investigated by means of FE-SEM, XRD, XPS, and TEM (FIB), etc.

Fig.1 Reflective spectra of multi-layered Sn/Ag<sub>3</sub>Sn and Sn/Ag<sub>3</sub>Sn/Ag films before and after heating at 373 K for 120 h.

# Synthesis of ZIF-8 metal organic framework thin film on ZnO nanorods

Metal-organic frameworks (MOFs) are porous solid materials formed by coordination bonds between metal ions or clusters and organic linkers. Although they have already wide applications, their combination with other functional materials results in the formation of new multi-functional hybrid materials with combined or synergistic properties of the individual components. These new nanohybrid materials with novel properties expand the applications of metal organic frame works.

Here, we present a new method to synthesize thin films of the well-known metal organic framework ZIF-8 on zinc oxide nanorods. 2-methyl imidazole solution was casted on electrochemically grown zinc oxide nanorods on fluorine-doped tin oxide glass. Casting a thin film of the linker solution on the zinc oxide nanorods allows the underlying morphology to be preserved, leading to the facile and precise formation of nanostructured hybrid materials under short reactions times and conventional heating. This method allows for the fast and facile formation of nanostructured metal organic framework-semiconductor nanohybrid thin films with minimum use of both solvents and linker. We also present the effect of various synthesis parameters on the morphology of the resulting thin film, and the role of solvent.

# Electroless Deposition of Amorphous Nickel–Tungsten–Phosphorus Alloys with Superior Resistance to Crystallization

Amorphous nickel (Ni) alloys such as nickel-phosphorus (Ni–P), deposited using electroless plating, are applied as non-magnetic under-layers in heat-assisted magnetic recording (HAMR) devices. However, during subsequent processing and end use, the amorphous Ni layers are exposed to high temperature, which causes crystallization and undesired ferromagnetism. In this study, we fabricate and characterize *ternary* Ni alloys, such as nickel–tungsten–phosphorus (Ni–W–P), with improved resistance to crystallization.

First, we developed an alkaline electroless deposition process for fabricating Ni–W–P thin-films with tungsten content in the 1–3 atomic % range. During electroless Ni–W–P deposition, the electrochemical kinetics of the oxidation and reduction half-reactions and their interdependencies were characterized using polarization measurements on a rotating disc electrode. Using differential scanning calorimetry, we characterized the crystallization temperature of Ni–W–P films. We found that increasing the tungsten fraction increases the crystallization resistance. Potential physical origins of this phenomenon will be discussed.

# Metallic Glass Coatings for Aluminum Current Collectors – Corrosion Inhibition

Pei-Yu Lai<sup>1</sup>, Jinn P. Chu<sup>2\*</sup>, Bing-Joe Hwang<sup>3</sup>

Has known to the public, corrosion of current collectors would lead to a gradual increase in internal resistance of cells and, in consequence, cause the fading of capacity and shorten the battery life. Aluminum has been the material of choice as cathode current collectors for lithium batteries since its native oxide layer could help resist corrosion. However, the oxide film still suffers from corrosion problem especially under high operating voltages. Metallic glasses (MGs) are expected to be promising materials for corrosion inhibition due to the absence of grain boundaries. So, to circumvent this corrosion issue, we use MGs as inhibitors to prevent Al current collectors from degrading in lithium ion batteries.

In this presentation, MGs are deposited on Al foils by magnetron sputtering. The MGs systems chosen include Zr- and W-based. We compare the outcomes of corrosion phenomena on Al foils with different MGs systems from proceeding electrochemical tests and surface analyses. The thickness effect is also discussed in the study.

**Keywords:** Metallic glass coating, lithium battery, Al current collector, corrosion

# Local Measurement of Hydrogen Diffusion in Steel Sheet

Yudai Yamamoto<sup>1</sup>, Misako Jin<sup>1</sup>,

<sup>2</sup>*Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060-8628, Japan  
kfushimi@eng.hokudai.ac.jp*

During the atmospheric corrosion of the steels, hydrogen atoms are absorbed into the steel and often initiate the deterioration of mechanical properties of the steels, inducing hydrogen embrittlement. For inhibiting hydrogen embrittlement, it is necessary to elucidate mechanism and kinetics of not only absorption but also diffusion of hydrogen atoms in steel. Conventionally, diffusion coefficient of hydrogen atoms in steel sheet samples was estimated using Devanathan-Stachurski (DS) double electrochemical cell [1]. The DS cell method enables only to measure currents of hydrogen entry and exit side cells, the difference of which corresponds to hydrogen atoms permeated into the sample. Compared with the entry current, however, the exit current was very small and then it was difficult to use DS cell in the case of local measurement.

The authors have modified the DS cell with a flow channel in the entry side cell and discovered that the perturbation in the flow-rate causes the changes in the hydrogen exit current  $i_{\text{exit}}$  as well as hydrogen entry current  $i_{\text{entry}}$  [2]. When a sine wave was used for the perturbation,  $i_{\text{entry}}$  and  $i_{\text{exit}}$  showed similar waveforms with phase shifts depending on the perturbation frequency. The phase shift was arisen from diffusional delay in  $i_{\text{exit}}$  and was expected to be a new parameter to discuss the diffusivity of hydrogen atoms in the samples. In this study, a micro-capillary cell technique was also applied to the modified DS cell to realize local measurements. Furthermore, a series of finite element method (FEM) numerical calculations were conducted for the simulation and the estimation of the diffusion of hydrogen in the steel sheet, assuming that both hydrogen entry and exit reactions were in mass-transport limitation and the phase shift was only arisen from the diffusion.

The DS cell with a micro-capillary cell of an inner diameter of 250  $\mu\text{m}$  was successfully applied to measure the local hydrogen permeation into a single grain or two grains of a mild steel sheet with a thickness of 100  $\mu\text{m}$ . During the sinusoidal perturbation in the entry side cell, the phase shift on a single grain was two times larger than that on the grain boundary. It was indicated that the hydrogen permeation was accelerated due to existence of the grain boundary. From the comparison with theoretical diffusion equation of hydrogen in the steel sheet sample [3], it was revealed that the diffusion coefficient on the grain boundary was at least two-times larger than that in the single grain. These results suggested that the metallurgical structure of steel substrate strongly influenced to the hydrogen permeation. The FEM calculation of two- and three-dimensional diffusion problems also revealed that the fluctuation in the flow-rate of the electrolyte solution gave rise to the phase shift of current waves depending on the diffusivity in the substrate. The difference in phase shift due to local diffusivity was simulated as well as the size effect of local substrates where hydrogen atoms were permeated.

# **Alloy Anodization in Fluoride-Containing Electrolytes**

Hiroaki Tsuchiya, Min-Su Kim, Toshiaki Erami, Yuki Otani, Shinji Fujimoto  
*Division of Materials and Manufacturing Science, Graduate School of Engineering, Osaka University*  
*2-1 Yamada-oka, Suita, Osaka 565-0871 Japan*  
*tsuchiya@mat.eng.osaka-u.ac.jp*

Properties and structures of oxide layers, including passive films, on metals and alloys can be tuned by tailoring electrochemical conditions. It is well-known that the morphology of oxide layers can be also controlled by electrochemical approaches. Among the approaches reported, anodization is one of the most established examples, where self-organized nanoporous oxide layers are formed on aluminum substrate by electrochemical anodization in acidic electrolytes. In the decades it has been reported that self-organization takes place – the formation of self-organized nanoporous and nanotubular oxide layers – on the other metals such as titanium, zirconium, tantalum etc. by anodization. The key to achieve such self-organization is to treat in a small amount of fluorides under optimized conditions and the morphology (diameter and thickness) of oxide layers are varied depending not only on anodization condition but also on substrate. Therefore, anodization to form the self-organized nanostructures has been applied for a variety of substrates. The present work reports alloy anodization in fluoride-containing electrolytes, focusing on how microstructure and chemical composition of alloy affect the growth and morphology of oxide layers.

# Corrosion studies using non radioactive isotopes of H, Zn and Fe

Achim Walter Hassel<sup>1,2</sup>, Martina Hafner<sup>1</sup>, Bernhard Gallistl<sup>2</sup>

*1 Christian Doppler Laboratory for Combinatorial Oxide Chemistry at the*

*2 Institute for Chemical Technology of Inorganic Materials,*

*Johannes Kepler University Linz, 4040 Linz, Austria*

Investigations with isotope enriched materials are amongst the most intriguing ones in chemistry. Typically such materials are rather expensive due to the tedious enrichment process. The price can easily reach 1000 € per gram for a material with an isotopic enrichment of 98 % or more. This is for example the case when highly enriched <sup>57</sup>Fe is used. One example will illustrate how this non radioactive isotope can be used in designing experiments for studying complex corrosion processes in which more than one source exists for the element of interest.

Hydrogen exists in three isotopes and is the only element that has different names and symbols for these named protium H, deuterium D and tritium T. While the latter is radioactive the first two are not. The reason for these different names is probably due to relatively easy way for high enrichment at an affordable price at least for H and D. Besides this the isotopic effect is much stronger than for any other element due to the large relative mass change of 100 % from H to D. In an attempt to better understand the different oxide products that form on press hardened galvanized steel [1] artificial corrosion product were synthesized from both light and heavy water solutions H<sub>2</sub>O and D<sub>2</sub>O to yield deuterised corrosion products such as simonkolleite, hydrozincite and akaganeite. IR transmission spectroscopy was used to characterize these products and to quantify the shift in wavenumbers of bonds with modified reduced mass. Standard addition NMR spectroscopy was used to quantify the unavoidable H/D exchange during preparation.

Zn being one of the most important elements in corrosion science is also of high interest for such studies. As one example the structure of a passive film forming under alkaline conditions on the amphoteric zinc depends on the pH of the solution. Not only zinc oxide and hydroxides play a role but also more complex zinc corrosion products such as hydrozincite, simonkolleite or akaganeite may be formed if the other elements are present. Even in trace amounts zinc can influence the following processes due to its ability for underpotential deposition, which are not only of academic interest but also of technical relevance e.g. for the crystallography of technical coatings. Also corrosion inhibitors may contain Zn as constituent. In cases in which processes are combined it may be unclear but of interest how much zinc originates from the one or the other source. Thus it might be necessary to distinguish zinc from zinc, something that is chemically not possible. Inductively coupled plasma mass spectrometry (ICP-MS) is a modern way for distinguishing various isotopes. For experiments with Zn a pure Zn isotope may be used but there is a much smarter way. Natural zinc consists of 48.6 % <sup>64</sup>Zn, 27.9 % <sup>66</sup>Zn, 4.1 % <sup>67</sup>Zn, 18.8 % <sup>68</sup>Zn, 0.6 % <sup>70</sup>Zn isotopes (in at.%). Since zinc is used in dissolved form as corrosion inhibitor in cooling water circuits, also nuclear power plants. However, neutron capture converts <sup>64</sup>Zn into <sup>65</sup>Zn which decays over <sup>65</sup>Cu by a hard  $\gamma$ -ray radiation. Therefore Zinc which is used in nuclear power plants is intentionally depleted in <sup>64</sup>Zn (< 1%) before use and is called DZO (depleted zinc oxide). The approach described here does not make use of pure monoisotopic zinc; it rather simply uses zinc with a strongly deviating isotope pattern. When combined with flow type scanning droplet cell microscopy FT-SDCM electrochemical depth profiling becomes possible that distinguishes zinc from zinc [2].

# Analysis of Corrosion Behavior of ASTM A416 Steel by Electrochemical Impedance Spectroscopy

Yu-Min Chen and Mark E. Orazem  
*Department of Chemical Engineering*  
*University of Florida, Gainesville, FL 32611 USA*  
[meo@che.ufl.edu](mailto:meo@che.ufl.edu)

During the past few decades, segmental bridges incorporating post-tensioned tendons have been widely adopted for bridge construction because they can withstand heavier loads and allow for longer spans. However, corrosion of the steel tendons has become a significant problem, leading, in some cases, to structural failure.

The corrosion behavior of ASTM A416 steel was studied in a simulated pore solution<sup>1</sup> containing 2 g/L  $\text{Ca(OH)}_2$ , 8.33 g/L NaOH and 23.3 g/L KOH with a pH of 13.8. Experiments were conducted using a traditional three-electrode setup. The ASTM A416 steel working electrode was polished sequentially with #120, 320 and 600 grit silicon carbide papers. The working electrode was subsequently degreased with ethanol and washed with water before each experiment. The counterelectrode consisted of a 5 mm  $\times$  50 mm platinum sheet, and an Mg/MgO reference electrode was used to avoid possible chloride contamination. The electrolyte temperature was maintained at 298 K by a temperature controller. The dissolved oxygen content was maintained at 8ppm by sparging ultra-high-purity-grade air.

The time required to reach steady-state was found to depend on potential. Generally, a steady open-circuit potential was reached after 200ks (56 h). For -0.1V (OCP), 50ks (14 h) was required to reach steady state; whereas, at +0.3V (OCP), 250ks (69 h) was required. Electrochemical impedance spectroscopy (EIS) was measured at different elapsed times with a frequency range 500Hz – 0.05Hz. Once a steady-state was reached, EIS measurement were performed at different potentials ranging from -0.3V to +0.3V (OCP). The low-frequency EIS results show a straight line between 22.5° to 45°, suggesting the influence of a porous electrode behavior. The process model included an ohmic resistance ( $R_e$ ) in series with a parallel combination of an anodic reaction impedance ( $Z_a$ ), a cathodic reaction impedance ( $Z_c$ ), and a constant phase element. Measurements at  $\pm 50\text{mV}$  were used to confirm that both the anodic and cathodic impedances played a role in the model.

The process model allowed estimation of oxide film thickness and corrosion rate. The oxide film thickness was estimated from CPE parameters using the power-law model developed by Hirschorn et al.<sup>2</sup> The oxide film thickness was estimated to be 15 nm for potentials from -0.3V to 0.2V (OCP). At more anodic potentials, +0.3V (OCP), the oxide film thickness was found to be 25 nm. The corrosion rate was estimated from the anodic charge-transfer resistance extracted from the process model. The corrosion rate at the open-circuit potential after an elapsed time of 2 hours (7.2 ks) was estimated to be 64  $\mu\text{m}/\text{year}$ . A statistically significant value for the anodic charge-transfer resistance could not be obtained after steady-state was reached, thus the corrosion rate could not be calculated. Similarly, the steady-state corrosion rate could not be estimated for potentials smaller than +0.3V (OCP). The steady-state corrosion rate at +0.3V (OCP) was estimated to be 50  $\mu\text{m}/\text{year}$ .

pkeech@nwmo.ca

The use of copper as a barrier against corrosion in deep geological repositories (DGRs) for used fuel containers (UFCs) has been explored in Europe, Asia and Canada for many decades, as metallic copper provides thermodynamic stability against anoxic corrosion. Extensive review of corrosion data reveals that damage will be limited to nanometres per year or less, or fewer than 1.3 mm in one million years<sup>1</sup>. In recent years, Canada's Nuclear Waste Management Organization (NWMO) has been developing methods for depositing thin copper coatings of copper directly onto steel-based UFC materials that provide suitable strength to withstand geological processes for many years. The result is the NWMO Mark II UFC, shown in Figure 1, both as a schematic and as a fabricated prototype. This container offers many potential manufacturing and handling advantages, owing to its modest size and low weight; the container depicted is just over 2 m long and < 5 t fully loaded, and compares favourably to a loaded KBS-3 container (> 4 m long and > 25 t)<sup>2</sup>.

**Figure 1: NWMO Mark II Used Fuel Container (a) Schematic and (b) Prototype**

Electrodeposition and cold spray have been explored for container production, with the former proving to be superior for pre-fabrication (i.e. empty containers/lids), while the latter offers advantages for completing the coating over the closure zone, following weld sealing of a loaded container. As the corrosion barrier, it is necessary for the copper coatings to perform as well (or better) than wrought copper materials, for which a large copper corrosion database exists. Corrosion testing of the coating materials has been extensive, consisting of long term exposures to oxic and anoxic conditions as well as accelerated electrochemical measurements. Coating materials have demonstrated corrosion performance that is similar to that of the wrought copper reference materials, with the exception of the accelerated testing in which there are subtle differences among the materials with respect to surface texturing, observed via post-experiment surface analysis. However, throughout the experiments, there is consistency among corrosion potential measurements for the coating and wrought materials, as these fall within a few mV of each other under different conditions such as oxic and anoxic exposures and in accelerated electrochemical measurements. An example is presented in Figure 2, for an experiment that was initially oxic and then anoxic. Results from all of these experiments and the supporting surface analysis, will be described in this paper.

**Figure 2: Corrosion Potential versus time plot for the samples exposed initially under O<sub>2</sub> purging, then followed by Ar-purging**

# Electrochemical behavior of electrodeposited Ni-W nanostructured alloys

N. Shakibi Nia, M. Lagarde, J. Creus, X. Feaugas, C. Savall

*LaSIE UMR 7356 CNRS, Université de La Rochelle, Av. Michel Crépeau, 17042 La Rochelle, France.*

*Email address: [niusha.shakibi\\_nia@univ-lr.fr](mailto:niusha.shakibi_nia@univ-lr.fr), [xavier.feaugas@univ-lr.fr](mailto:xavier.feaugas@univ-lr.fr)*

Nanocrystalline electrodeposited coatings have been the subject of numerous studies due to their supposed resistance against corrosion and their particular mechanical, electrical and magnetic properties. However, the superior corrosion resistance of lower grain size metals, particularly at the nanometer scale, has not been yet clearly established [1]. Actually, as grain size decreases, other parameters like surface roughness, crystallographic orientation, chemical contamination, vacancies concentration, internal stresses at different scales ..., which can affect the corrosion resistance, are also modified. The aim of our approach is to better understand the influence of the microstructural parameters, mainly grain size and tungsten content, on the corrosion resistance.

Additive free citrate-ammonium bath is used to obtain Ni-W alloys, by applying direct and pulse currents. In order to extend the grain size range conserving the alloy element content constant, some of these coatings were annealed under vacuum conditions at various temperatures during one hour. A multi-scale characterization of the metallurgical states of electrodeposited nanocrystalline coatings using a combination of several microstructural techniques (DSC, XRD, SEM, EBSD, TEM and AFM) has permitted the characterization of the morphology, the grain size, the crystallographic texture and the nature of grain boundaries. These complementary techniques permit to define transition scales that are necessary to discuss the physical meaning of the different microstructural features [2]. The influence of deposition parameters on chemical contamination by light elements is evaluated by Secondary Ion Mass Spectrometry (SIMS) analysis and the amounts of these elements are quantified systematically by hot extraction measurements [3]. At last, polarization curves were used to study the anodic behavior and the kinetics of the Hydrogen Evolution Reaction in acidic ( $\text{H}_2\text{SO}_4$  1M, pH 3) and alkaline (NaCl 0,6M, pH 10) deaerated solutions.

According to our results, the grain size refinement strongly depends on the elaboration parameters (current density, temperature, electrodeposition bath composition ...) which also influence the light elements contamination (O, H, N, C) and/or the alloying addition. The analyses of the polarization curves in acidic media revealed that the tungsten addition promotes the dissolution of the protective passive film and favors the localized corrosion in alkaline media. It is suggested that the tungsten addition plays an important role on the electrochemical reactivity in both anodic and cathodic domains and that the other metallurgical parameters such as grain size intervene only at second order.

In the framework of new ecological challenges, many plant extracts appear as promising green corrosion inhibitors. Their efficiency is generally attributed to the antioxidant properties of secondary metabolites, as flavonoid molecules, which are produced by plants in order to fight against environment attacks. However, due to the large number of molecules contained in plant extracts, the corrosion inhibition mechanisms remain largely unknown.

Table 1: Chemical formulae of the model flavonoid molecules

In acidic medium, the electrochemical impedance spectroscopy (EIS) measurements performed in HCl at pH 1 in water/ethanol medium show that the inhibiting properties through an adsorption mechanism are directly linked to the antioxidant activity of molecules which was determined by the ABTS test. Actually, the best inhibition efficiency is obtained with rutin characterized by two adjacent OH groups on the B-ring (catechol group), which also explains the radical scavenging activity and the chelation of metallic cations (especially  $\text{Fe}^{2+}$ ).

In more alkaline medium, at pH 4, the corrosion behavior is governed by the formation of a tri-dimensional conversion film made of iron and flavonoid, as revealed by SEM observations.

Fig 2: Passive films formed at pH4 in presence of rutin on steel (peeled off part)

This paper focuses on the inhibiting effect on steel corrosion of three model flavonoids with various antioxidant properties: naringin, neohesperidin and rutin.

Fig. 1: EIS measurements (Bode plot) of steel immersed in HCl (pH1, water/EtOH medium)

For a deeper understanding, compounds were synthesized from precipitation at pH 4 of iron salt in presence of flavonoid molecules and investigated by Raman spectroscopy and X-ray Absorption Spectroscopy measurements (XAS). Results show that the formation of conversion products requires the coordination of  $\text{Fe}^{3+}$  by the two O atoms attached to the B ring. From an electrochemical point of view, a cathodic inhibition attributed to the oxygen scavenger role of the antioxidant molecules was observed. Nevertheless, the anodic protection depends on the covering properties of the conversion film (when it is formed), related to the molecule structure.

# Towards high-throughput Corrosion Screening using Bipolar Electrochemistry

Sara Munktell, Leif Nyholm, Fredrik Björefors

*Department of Chemistry - Ångström Laboratory, Uppsala University,  
Box 538, SE-75121 Uppsala Sweden  
e-mail: sara.munktell@kemi.uu.se*

In this work the concept of using arrays of bipolar electrodes for a fast and simple way to screen corrosion properties is presented.

When an isolated conducting object is exposed to an external electric field the resulting potential difference across its surface can cause part of the total current to pass through said object. The result of this is that the object will act as an anode and a cathode simultaneously and that there will be a gradient in electrochemical potential ranging between the two end poles. The effect has proved useful in various industries and research fields with applications ranging from large scale chemical reactors to the modification of nano-objects<sup>1</sup>.

We have previously demonstrated that bipolar electrochemistry can be used to generate gradients in corrosion damage on steel samples to evaluate their corrosion properties<sup>2</sup>. When a number of steel samples are placed together in an array configuration and subjected to an external field they all act as individual bipolar electrodes, and in this way many samples can be compared in the same experiment at the same time. The shape of the gradient that forms on the anodic end of the samples will depend on the steels corrosion resistance.

When all steel samples placed together are of the same type the BPE-induced gradients are all alike. If steels of different corrosion properties are placed together the least resistant steel will pass more of the current and therefore corrode further<sup>3</sup>. This effect can be used to enhance differences between samples. An example of this is shown in Figure 2.

Figure 1: Schematic of the BPE-array setup.

Figure 2: Gradients on the same type of steel from different setups, arrows roughly indicates the length of the gradient.

# Photo-electrochemical degradation of anodized titanium surface observed using EIS and ellipso-microscopy

Titanium alloys are known well as highly corrosion resistive materials and are used in chemical plants and seashore. It is mainly due to the formation of passive oxide film that is chemically stable in corrosive environment for general materials. However, the oxide of titanium alloy has an n-type semiconductive property and structure of anatase, which is frequently used as a photo-catalyst in various fields. Therefore, it is important to consider the degradation behavior due to photo-assisted corrosion of titanium alloy used in the sunshine.

Electrochemical impedance spectroscopy (EIS) and ellipso-microscopy of titanium electrode anodized in sulfuric acid solution were carried out during the irradiation of ultra-violet (UV) light with a wavelength of 325 nm. EIS revealed that the UV-light irradiation of the anodized surface induced a photo-electrochemical reaction of the titanium oxide film on the surface as well as oxygen evolution. A charge transfer resistance increased in the initial stage and then decreased, while a film capacitance increased continuously. The change of the film was dependent on the applied potential during the irradiation. Furthermore, ellipso-microscopy gave a series of heterogeneous images of the oxide film, depending on a crystallographic texture of the titanium substrate. The basal plane of 0001 tended to be covered with a relatively thin oxide film, which was changed dramatically by the irradiation.

A localized UV-light irradiation of anodized titanium surface with a photo-mask allowed the selective change of the oxide film as shown in Figure 1. It is suggested that the local irradiation is effective not only to fabricate a pattern on the surface but also to modify the surface homogeneously. The later might be beneficial to improve a corrosion resistance of the titanium.

Figure 1. Locally damaged titanium surface by irradiation of UV-light with a mesh.

# Passivation Behavior of Type-316L Stainless Steel in the Presence of Hydrogen Sulfide Ions Generated from Liquid-Phase Ion Gun

Junseobl@cse.hokudai.ac.jp

Passivation and depassivation of stainless steels in sulfide-containing environment such as crude oil and gas wells have become of particular interests for practical applications [1]. Hydrogen sulfide ion ( $\text{HS}^-$ ) is an aggressive anion and forms a sulfide layer on the stainless steel surface. The sulfide layer shows protective or non-protective properties depending on the corrosion reaction [2, 3]. It is important to understand passivation and depassivation in a presence of  $\text{HS}^-$ . Recently, the authors have developed a liquid-phase ion gun (LPIG) to release an infinitesimal amount (ppm-order) of  $\text{HS}^-$  by reducing a silver/silver sulfide microelectrode and applied to induce the local sulfidation on a silver surface [4]. The application of LPIG enables to elucidate the passivation and/or depassivation of stainless steels induced by hydrogen sulfide ions. In this study, effects of  $\text{HS}^-$  on passivity of type-316L stainless steel were examined by using LPIG for the first time.

The fabrication procedure of a silver/silver sulfide LPIG microelectrode was basically identical with that reported previously [4]. A diameter of the microelectrode was 500  $\mu\text{m}$ . A three-electrode electrochemical cell with a platinum counter electrode and an Ag/AgCl/sat. KCl reference electrode (SSE) was used for electrochemical measurements of a substrate electrode of the stainless steel. The surface of the stainless steel was passivated by a potentiostatic polarization at 0.9  $V_{\text{SSE}}$  for 100 s. When a distance between microelectrode and substrate electrode was sustained with 125  $\mu\text{m}$ , the microelectrode was connected with the substrate electrode and galvanostatically reduced to generate  $\text{HS}^-$  by using a battery-driving DC signal source in pH 8.4 boric acid-borate buffer solution, while the substrate stainless steel electrode was continuously polarized at 0.9  $V_{\text{SSE}}$ . Electrochemical impedance was measured at a constant frequency of 15 Hz and in a frequency range of  $10^{-2}$  to  $10^4$  Hz with an amplitude voltage of 10 mV. Moreover, silver wire and tungsten wire electrodes were used to estimate concentration of  $\text{HS}^-$  and pH value, respectively, in the narrow space between microelectrode and substrate electrode before and after the galvanostatic polarization of LPIG microelectrode. Auger electron spectroscopy (AES) was also used to analyze the passive film on the stainless steel when it was formed with or without presence of  $\text{HS}^-$  generation by LPIG.

From the open circuit potential measurement of the silver and tungsten wire electrodes during the LPIG polarization for generation of  $\text{HS}^-$ , concentration of  $\text{HS}^-$  and pH values in the narrow space were estimated with less than 10 ppm and ca. pH 9.5, respectively. During potentiostatic polarization of the stainless steel and LPIG microelectrode, current density increased with increase in concentration of  $\text{HS}^-$ . It is considered that further reactions could be induced by  $\text{HS}^-$  during the passivation of the steel surface. The impedance at 15 Hz increased during the polarization in the presence of  $\text{HS}^-$  by LPIG, while that continuously decreased after stopping the generation of  $\text{HS}^-$  and removing the microelectrode to the solution bulk because of [a](#)-dilution of  $\text{HS}^-$ . Moreover, a charge transfer resistance of passive film formed in the presence of  $\text{HS}^-$  increased with increase in  $\text{HS}^-$  concentration. AES revealed that the S-containing layer formed with  $\text{HS}^-$  was thicker than that formed without  $\text{HS}^-$ . It was demonstrated that the passive layer formed on type-316L stainless steel at 0.9  $V_{\text{SSE}}$  in pH 8.4 buffer solution was stabilized by the presence of  $\text{HS}^-$ .

Nadine.Peber@ensiacet.fr

Since the beginning of the 1990s, the high toxicity associated with chromates has imposed restrictions on their use in industrial applications. As a consequence, intense research efforts are being undertaken to find new environmentally friendly compounds as corrosion inhibitors of aluminium and aluminium alloys. It was shown that 8-HQ acts as an effective corrosion inhibitor for different metals and alloys, such as magnesium [1], copper [2] and aluminium [3-5]. Fig. 1 shows the chemical structure of 8-HQ. The molecule contains nitrogen, oxygen heteroatoms and aromatics rings which are the basic requirements for inhibitive action.

Fig. 1: Molecular structure of the 8-HQ (C<sub>9</sub>H<sub>7</sub>NO)

The aim of the present work is to investigate, at atomic scale, the corrosion inhibition mechanisms of 8-HQ on pure aluminium surfaces by using *ab initio* calculation. The final goal of the study was to correlate theoretical approach to experimental ones (electrochemical data and surface analysis) in order to extract the factors which are favourable to the inhibition processes. A better understanding of the corrosion inhibition mechanisms will help to rationalize the search of new species that could provide corrosion protection close to that afforded by chromates.

Density functional theory (DFT)-based concepts were used to investigate the adsorption of the 8-HQ and its derivatives that could be present in acidic, alkaline or neutral media, *i.e.* the 8-HQ tautomer and dehydrogenated species. The Al(111) surface was modelled by a periodic slab and dispersed corrected computations were performed and discussed, in term of adsorption sites and adsorption topology. A detailed electronic structure analysis of the molecule (charge transfer, density of states, partial charges) led to the determination of the nature of the bonding (physisorption or chemisorption) and to the characterization of the molecule/metal interface that is really meaningful because the surface properties of the system depends on the bonding. In parallel, electrochemical measurements were performed on pure aluminium in an aqueous solution for different pH (from 3 to 10). It was shown that in acidic or alkaline solutions, 8-HQ decreased the uniform corrosion rate of the aluminium indicating an adsorption mechanism on the bare surface whereas in neutral solution the dissolution mechanism was modified showing that the inhibitor interacts with the aluminium oxide and the passive layer was strengthened.

Khurram5433@outlook.com

Magnesium and its alloys have growing interest as structural materials for aerospace, electronics and automotive industries, owing to their low density and high strength/weight ratios, and therefore are considered as alternatives to aluminum alloys. However, poor corrosion resistance of magnesium limits their applications. Surface treatments, including anodizing, are needed for their practical applications, and in contrast to many anodizing metals such as aluminum, titanium, niobium etc, the studies on growth behaviour of the magnesium in aqueous electrolytes are limited because of difficulty of uniform film formation in these electrolytes. Recent studies on magnesium disclose that the corrosion of magnesium in ethylene glycol (EG) solution can be improved by fluoride addition as a consequence of the formation of a protective film [1]. Habazaki *et al.* and Hernandez *et al.* reported recently the formation of fluoride-based barrier-type anodic film on magnesium at high efficiency in organic electrolytes containing water [2, 3]. Despite these recent advances, no report on the formation of barrier type film on magnesium at high efficiency in aqueous electrolyte is present. Therefore, in the present study the influence of water concentration on film growth efficiency is examined in EG-water electrolytes containing phosphate and fluoride.

Magnesium films of 220-230 nm thickness were prepared by DC magnetron sputtering on flat anodized aluminum and glass substrate. Sputtered films were anodized at a constant current density of 10 A m<sup>-2</sup> to the selected voltages in EG-water electrolytes containing phosphate and fluoride with various concentrations of H<sub>2</sub>O at 293 K. Anodizing was also performed in phosphate free and phosphate containing aqueous electrolytes. Electron microscopies (SEM and TEM) were used for the investigation of surface and cross section of anodic films, while X-ray diffraction and Rutherford backscattering spectroscopy were employed for film structure and composition respectively.

Figure 1 shows an example of the surface and cross section of the anodic film formed in phosphate containing aqueous electrolyte. It is obvious that anodic film shows smooth surface with flat and parallel metal/film and film/electrolyte interfaces even in EG-free aqueous electrolyte. The thickness of anodic film estimated from TEM is 113 nm, which corresponds to the formation ratio of 1.13 nm V<sup>-1</sup>, whereas this formation ratio was 1.8 nm V<sup>-1</sup> in EG-0.18 vol. % water, indicating large influence of water concentration on formation ratio. XRD and selected area diffraction pattern disclosed that structure of anodic film was amorphous in EG-0.18 vol% water and transform to crystalline phase at water concentration  $\geq 10$  vol. %. RBS analysis revealed that film efficiency was reduced from 100 % in EG-0.18 vol% water to approximately 50% in aqueous electrolyte, while film composition is not largely affected with increasing water concentration.

Fig. 1 (a) Surface SEM and (b) cross-sectional TEM images of an anodic film formed on the sputtered magnesium film to 100V in aqueous electrolyte containing 0.1 mol dm<sup>-3</sup> NH<sub>4</sub>F and 0.1 mol dm<sup>-3</sup> K<sub>2</sub>HPO<sub>4</sub> at 293 K.

# Assessing Uniform Corrosion of Aluminum Alloys 2024-T3, 6061-T6, and 7075-T6 in Aqueous Immersion Conditions

I-Wen Huang, Rudolph G. Buchheit  
*Fontana Corrosion Center, The Ohio State University*  
2041 N. College Rd. Columbus, OH 43210  
[huang.697@osu.edu](mailto:huang.697@osu.edu)

High strength aluminum alloys are known to be particularly susceptible to localized corrosion induced by heterogeneous intermetallics, but the ability to quantitatively assess uniform corrosion along with pitting has become a major challenge for pit growth prediction. [1] The pit depth measurement is shown to be affected by reference surface changing due to uniform corrosion as well as pit agglomeration. Therefore, the ability to measure pit depths and uniform corrosion simultaneously by profilometric methods to compensate for the reference surface recession has become a critical correction needed in aqueous conditions.

In this work, pitting corrosion and uniform dissolution of aluminum alloys 2024-T3, 7075-T6 and 6061-T6 were characterized quantitatively using optical profilometry (OP) after free immersion in 0.01 to 1.0 M NaCl solutions as a function of pH (3, 5, 8, 10), temperature (20, 40, 60, 80°C) and exposure time (1 day, 1 week, and 1 month). Samples were cut into 1 cm<sup>2</sup> coupons and then partially painted by lacquer to keep intact surface free from corrosion. Uniform dissolution was estimated by carefully measuring the step height between the masked surface and the exposed surface along with pitting information including pit depth, diameter, area, and volume. The influence of pH, chloride ion concentration, and temperature will be discussed in detail.

This investigation of uniform corrosion is supported by electrochemical experiment where cathodic limiting current was slowed by the reduced oxygen solubility at elevated temperature. Electrochemical impedance spectroscopy (EIS) results also show elevated polarization resistance at high temperature from 10<sup>4</sup> to 10<sup>9</sup> (ohm·cm<sup>2</sup>) and potentiostatic tests show that pit initiation frequency was much lower at high temperature. It was also found that a passive film formation creates a surface inert to oxygen reduction reaction during a long term immersion, which was not seen in short term electrochemical tests, protecting the surface at high temperature conditions. Corrosion product and passive film analysis were performed by energy-dispersive X-ray spectroscopy (EDS) and electron diffraction. Samples prepared by focused ion beam (FIB) were examined to identify the composition and microstructure of corrosion product in both low and high temperatures.

In addition, to validate the proposed pit morphology influenced by uniform corrosion, long term sample immersion and B117 salt spray chamber tests were also employed. Maximum pit depth was carefully found and a detailed profile scan was conducted by OP. This pit profile obtained unveils the altering pit geometry with uniform corrosion. In this presentation, details of the experimental method and the results will be presented and the implication of these results on corrosion damage accumulation will be addressed.

# Micro-pattern Corrosion Screening on Bimetallic Corrosion for Microelectronic Application

Arindom Goswami, Po-Fu Lin and Oliver Chyan,  
*Interfacial Electrochemistry and Materials Research Lab*  
*University of North Texas*  
*Denton, Texas TX 76203*  
*Chyan@unt.edu*

As the miniaturization trend on integrated circuit continues, the minute dimensions ( $< 20$  nm) involved in advanced microelectronic device architecture can greatly accelerate the progression of on-chip corrosion into a severe reliability threat. In particular, various interfaces formed between multilayer film stacks can generate dissimilar contacts with significant galvanic potential differences to active on-chip corrosion under favorable semiconductor processing conditions. Currently, 10-13 layers of Cu interconnects provide digital communication framework within a modern 14 nm IC chip set. The Cu interconnects are fabricated by dual damascene patterning technique that utilizes chemical-mechanical planarization (CMP) process to remove excess Cu deposit. Furthermore, the increased noble character of new diffusion barriers like Ru can further intensify the Cu galvanic corrosion especially in CMP corrosive chemical environments. In electronic packaging area, heavy corrosion on Al bond pad in a Cu wire bonded assembly was identified as a critical failure mode. In some cases, corroded Al pad is subjected to positive bias and/or Cl contamination. Even though there can be one or more of factors such as chemical environments, bimetallic contacts and positive bias to activate the observed bimetallic corrosion, the exact corrosion activation mechanism(s) remain unclear; as such the effective corrosion prevention can't be achieved. In this paper, we report the research efforts to establish bimetallic corrosion mechanism(s) and explore effective prevention strategy using micro-pattern corrosion screening metrology combined with electrochemical and x-ray photoelectron spectroscopy (XPS) techniques. As illustrated in Fig. 1, patterns of Cu micro-dots were deposited, through a micro-dot mask, on selected barrier metal substrates including Ta, Ru, and Ta/Ru alloy. The Cu corrosion on the testing pattern was observed in real time under digital optical microscope to evaluate Cu corrosion rate in different chemical environments and record surface transformations of Cu corrosion. The corrosion screening reveals that Cu contacts with Ru leads to enhanced galvanic corrosion of Cu as compared to Cu/Ta. The corrosion mechanisms of Cu/Ru and Cu/Ta were established (Fig. 2) in various CMP related chemical environments. Our corrosion screening data showed pyrazole could inhibit Cu corrosion more effectively than benzotriazole in highly alkaline tetramethyl ammonium hydroxide solution [1]. In device packaging area, SEM/EDX and optical microscopy reveal the early state of Al/Cu bimetallic corrosion mostly follows the grain boundaries on an Al bonding pad. As such, better understanding where the corrosion starts and how erosion progresses under specific chemical environments will aid in the development of effective corrosion inhibition strategies for microfabrication application.

# Electrochemical corrosion behavior of permanganate conversion coating on AZ31B magnesium alloys — Long term evaluation by EIS

Shun-Yi Jian, Yueh-Lien Lee, and Chao-Sung Lin\*

Department of Materials Science and Engineering, National Taiwan University  
1, Roosevelt Road, Section 4, Taipei 106, Taiwan

\*Correspondent: csclin@ntu.edu.tw

The permanganate conversion coating on magnesium generally contains defects such as cracks, which deteriorate the coating adhesion and corrosion resistance.<sup>1-6</sup> As a result, in our previous study, we reported a new route to form a thin, nearly crack-free  $\text{MnO}_2$ -rich conversion coating on magnesium alloys.<sup>7</sup> The excellent properties of the permanganate conversion coating (PCC) treatment was performed in the solution composed of 0.1 M potassium permanganate ( $\text{KMnO}_4$ ), 0.025 M manganese nitrate ( $\text{Mn}(\text{NO}_3)_2$ ), and 0.02M potassium dihydrogen phosphate ( $\text{KH}_2\text{PO}_4$ ) at room temperature for 90 s. To further understand its electrochemical corrosion behaviors, the electrochemical impedance spectroscopy (EIS) technique is performed for coated magnesium alloys in this study, including permanganate conversion coating and commercial chromate conversion coating (Dow 1). The EIS measurement was conducted after immersion in 0.05 M NaCl and 0.1 M  $\text{Na}_2\text{SO}_4$  solution for different time periods up to 48 h. The EIS data in Fig. 1(a) as a function of immersion time reflected the evolution process of the permanganate coated AZ31B, including stages of the growth (0.5-24 h immersion) and the deterioration (30-48 h immersion) of the film. Similarly, the chromate coated AZ31B, including stages of the growth (0.5-18 h immersion) and the deterioration (24-48 h immersion) of the film. Thereby, the different electrochemical behavior of the conversion coated AZ31B is mainly due to their different properties and structure. Based on the EIS measurement, microstructure and composition analysis of the conversion coated AZ31B by SEM and TEM was also proposed for understanding the corrosion process of passive film. With the form of the impedance spectrum could be determined the mechanism of the corrosion process.

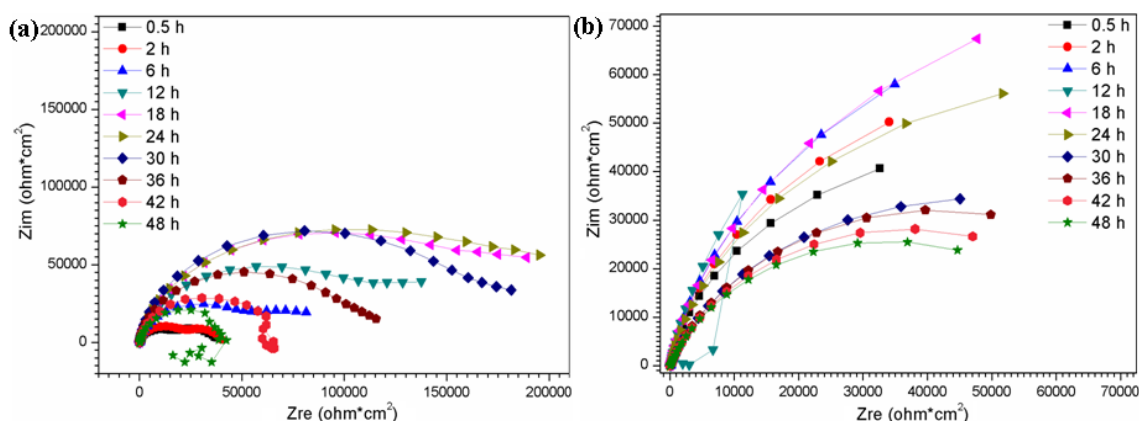

Fig. 1. Nyquist plots recorded on (a) permanganate and (b) chromate conversion coated AZ31B in 0.05 M NaCl and 0.1 M  $\text{Na}_2\text{SO}_4$  solution at various immersion times.

## Abstract

Local electrochemical impedance spectroscopy (LEIS) provides a rapid and *in-situ* imaging of surface of corroding systems with high spatial resolution, which provide the relevant information pertaining to the corrosion mechanism of metals in a variety of environments. Recent years, micro-electrochemical systems were developed to probe the localized corrosion behavior of metals/alloys, which could enable real time assessment, and provide corroborative evidences to understand the local corrosion process [1]. The present study focuses on the localized corrosion process at the damaged zone of epoxy coated steel in saturated  $\text{Ca(OH)}_2$  with varying concentrations of chloride ions. The LEIS measurements were performed over the defect ( $\sim 500 \mu\text{m}$ ) on epoxy coated steel using 50 mV amplitude potential. The microprobe with a  $10 \mu\text{m}$  tip was set directly above the damaged zone to measure its typical impedance response. The distance between the tip of the microprobe and the sample surface is  $\sim 50\text{--}100 \mu\text{m}$ . For 3D scanning, the microprobe was stepped over a designated area (X-Y axis) of the electrode surface. The excitation frequency for impedance measurements was fixed at 10 Hz for the line scan and 3D mapping. The degradation of the damaged zone of the epoxy coated steel in saturated  $\text{Ca(OH)}_2$  with varying concentration of chloride ions is monitored by measuring the change in localized  $|Z|$  (Figs. 1 (a, b, c and d)). The typical 3D mapping of the damaged zone in saturated  $\text{Ca(OH)}_2$  with 0.05 % NaCl is shown in Fig. 1(d). The line profiles and 3D mapping clearly indicate the decrease in  $|Z|$  with an increase in concentration of chloride ions while broadening of the line profile near the damaged zone indicates the increase in the extent of degradation of the damaged zone of the coated steel with an increase of concentration of chloride ions.

*Fig.1 LEIS line (a, b and c) and 3D profile (d) of the damaged zone of epoxy coated steel in Saturated  $\text{Ca(OH)}_2$  with varying concentration of chloride ions*

constanze.donner@atotech.com*

The immersion Au deposition on NiP – layers is a key process for PCB manufacturing. It is mandatory that parallel to the Au deposition a Ni- dissolution occurs to ensure an electron balance. Concurrent cathodic side reactions inducing moreover Ni dissolution should be suppressed just as the copper dissolution of exposed copper areas in case of insufficient Nickel plating at through hole and interconnect PCB structures.

The Nickel dissolution itself is preferable an inhomogeneous process with a sufficient number of active grain size to ensure at one hand good adhesion of the Au layer but avoid on the other hand a deep crevice corrosion. This balance depends via complex forming agents onto the dissolution rate of Nickel. Hereby it must be thoroughly distinguished between the effect of quasistationary complex concentration within the electrolyte and temporarily available increase of complex concentration at the surface due to its release from the Au complexes. Electrochemical quartz micro balance measurements combined with XRF and FIB investigations reveal the importance of concentration gradients onto the PCB substrates in the different stages of the Au immersion process starting from the induction period, via the Au deposition onto NiP to the Au deposition onto Au. The role of copper as galvanic coupling element and its control is discussed in this context..

# Zinc anodizing at high voltage in alkaline media

D. Veys-Renaux<sup>1,\*</sup>, E. Rocca<sup>1</sup>, K. Guessoum<sup>2</sup>

<sup>1</sup> Institut Jean Lamour, Université de Lorraine – CNRS, Faculté des Sciences et Techniques, 54500 Vandoeuvre les Nancy, France.

Micro-arc oxidation constitutes an interesting “green” alternative process in the field of surface treatments of aluminum, magnesium and titanium for about twenty years. It consists in a high-voltage oxidation beyond the dielectric breakdown occurring at the interface metal/oxide/electrolyte. Due to the high temperature reached in the resulting plasma, the grown coatings are dry ceramic layers, exhibiting interesting corrosion and wear resistance. This process is generally performed in alkaline media containing additives favoring both the growth rate and the corrosion resistance of the coated materials such as aluminates and silicates. This original paper focuses on the study of micro-arc treatments performed on zinc [1], which could lengthen the service life of sacrificial anodes.

An electrochemical study during zinc anodizing process revealed that the formation of the first stable insulating layer necessary to reach the dielectric breakdown (and therefore to initiate the sparks) is in competition with the dissolution of zinc. Therefore, beyond a maximum value of pH, starting with the micro-arc regime is no more possible. On the other hand, the addition of silicates or aluminates to the reference electrolytic bath (KOH 0.05 M) facilitates the occurrence of the sparking initiation: around 200 V in KOH 0.05 M, around 150 V with aluminates additives (0.05 M), around 100 V with silicates additives (0.05 M).

Fig.1: Potentiodynamic scans ( $15 \text{ V min}^{-1}$ ) performed on Zn in various alkaline media: effect of pH (a), effect of the presence of additives (b).

Post-treatment characterizations of the treated materials performed by FEG-SEM observations coupled with EDX analyses showed that the thickness, the morphology and the composition of the coatings highly depend on the anodizing voltage and the electrolytic bath composition.

Fig.2: Cross-sections observed after 15 min of potentiostatic anodizing: at 50 V in KOH 0.05 M +  $\text{Na}_2\text{SiO}_3$  0.05 M (a); at 50 V in KOH 0.05 M (b); at 150 V in KOH 0.05 M (c).

In terms of corrosion resistance, open-circuit potential measurements, potentiodynamic polarizations and electrochemical impedance spectroscopy measurements were performed in NaCl 0.1 M and showed a very slight improvement of the performances of the treated materials regarding an untreated one since the obtained coatings are cracked and dusty.

# Fabrication of super-liquid-repellent aluminum mesh with chemical etching/anodizing

Controlling the wettability of solid surfaces is of considerable importance in daily life and in industries. In particular, superoleophobic surfaces, on which oil droplets, as well as water, can keep spherical shape and roll off easily, have attracted much attention because of their superior properties, including icephobicity, corrosion resistance and so on. The authors have been fabricated superoleophobic surfaces that repel even octane droplets (surface tension: 22 mN m<sup>-1</sup>) on aluminum plate with micro/nano-dual pore structure, which has been introduced by chemical etching, anodizing, pore widening and fluoroalkyl coating [1]. In this study, we have introduced additional roughness of the order of 100  $\mu$ m by using Al mesh instead of Al plate. We observed further improved superoleophobicity for low surface tension liquids. In addition, we also examined liquid separation property of the hierarchical aluminum mesh with different coating layers to control the wettability.

Commercial aluminum mesh was chemically etched in aqueous solutions containing 0.2 mol dm<sup>-3</sup> CuCl<sub>2</sub> and 1 mol dm<sup>-3</sup> HCl to form micrometer-size half-cubic pits uniformly. Then, the etched specimen was anodized in 0.3 mol dm<sup>-3</sup> H<sub>2</sub>SO<sub>4</sub> at a constant voltage of 25 V for 180 s at 15°C to form a nanoporous oxide film and immersed in 5 wt% H<sub>3</sub>PO<sub>4</sub> for 900 s at 30°C to expand the size of nanopores. Finally, the specimen surface was coated with mono-[2-(perfluorooctyl)methyl]phosphate (FAP) or tetradecyl phosphate (TDP) layers simply by immersing in 1 mmol dm<sup>-3</sup> FAP or TDP/ethanol solution for 2 days.

Figs.1a-d show SEM images of aluminum mesh surface chemically etched, anodized and pore-widened. The hierarchical triple-pore structure including large pores of mesh, half-cubic etch pits and nanopores can be observed. The respective pore sizes are about 150  $\mu$ m, 1-2  $\mu$ m and 40 nm. After FAP coating, the hierarchical surface showed superoleophobicity as shown in Fig. 2. The surface revealed super-liquid-repellency even for hexane droplet (surface tension: 18 mN m<sup>-1</sup>) with advancing contact angle of 158° and the contact angle hysteresis of 3°. Although the FAP-coated surface was oleophilic with a contact angle of hexane on the flat surface was only 30°, superoleophobicity was successfully obtained by the introduction of such hierarchical surface morphology.

After TDP alkyl phosphate coating instead of FAP fluoroalkyl phosphate coating, the hierarchical aluminum mesh was superhydrophobic/superoleophilic. This mesh used successfully as a membrane to separate cyclohexane/water or rapeseed oil/water mixtures almost completely with only the organic liquids penetrating through the mesh. This separation is that water was perfectly repelled and oil passed through the mesh. In addition, the hierarchical aluminum mesh without organic coating separated also these oil/water mixtures if the surface was pre-wetted with water. In this case, water passed through the mesh and oil was almost-totally repelled. The separation efficiencies of both surfaces were approximately 95%.

Fig. 1 SEM images of the aluminum mesh (a) without treatment and (b-d) chemically etched, anodized and pore-widened.

Fig. 2 Liquid droplets on the superoleophobic aluminum mesh surface: 1. rapeseed oil, 2. hexadecane, 3. dodecane, 4. acetone, 5. ethanol, 6. octane, 7. 2-propenol, 8. hexane.

# Corrosion of Indium Tin Oxide Films in SiO<sub>2</sub> Solutions

Leo Chau-Kuang Liao\* and Jia-Lin Jhan

Department of Chemical Engineering and Materials Science, Yuan Ze University, Chung-Li  
32003, Taoyang city, Taiwan

\*e-mail: lckliu@saturn.yzu.edu.tw

Indium tin oxide (ITO) films show transparent and conducting properties and have been widely used as substrates for optoelectronic devices. The stability of the ITO films, such as corrosion in solution environments, was studied to understand corrosion mechanisms. In this work, we investigated the corrosion of ITO films in SiO<sub>2</sub> solutions when voltage was applied to the ITO electrodes in different time treatments at room temperature. The ITO films were put in both the anode (positive) and cathode (negative) electrodes in 1wt% SiO<sub>2</sub> solutions with setting 15V to the electrochemical system. Results showed that SiO<sub>2</sub> particles moved to and deposited on the anode electrode, whereas, the color of the cathode electrode changed from transparent to black. The black area on the ITO demonstrated non-conductive film by the current-voltage test. The properties of the treated cathode electrodes were further analyzed using analytical instruments to study the phenomena. The XRD spectra shows that strong ITO peaks were demonstrated for the electrochemical treatment for 0 and 1 minutes as shown in Figure 1. However, the XRD spectrum reveals the prominent peaks of metal In appear significantly after the sample treatment for 30 minutes as shown in Figure 1. The disappearance of ITO and formation of In XRD peaks as functions of time were also observed according to the XRD data. The surface morphologies of the cathode samples were demonstrated using the SEM images as shown in Figure 2. Small amount of the particles on the ITO surface were formed for 1 minute treatment as shown in Figure 2(a). Moreover, the In particles grew from the reductive reaction of ITO were displayed in Figure 2(b). The reductive corrosion mechanism of ITO was revealed and discussed in this study.

# Electrochemical Investigation on Passivation Characteristic of P110 Steel in Alkaline Solution

Chengqiang Ren, Ye Peng, Jiameng Li, Jingsi Hu, Bo Liu, Li Liu

School of Materials Science and Engineering, Southwest Petroleum University

Chengdu, 610500, P. R. China

chengqiangren@163.com

In order to understand the formation and damage of passive film on the surface of casing steel caused by alkaline solution at hydration stage and aggressive ion at corrosion stage respectively in the oil well, experiments were operated in the simulated concrete pore solution. Electrochemical behaviors, including electrochemical impedance spectroscopy, potentiodynamic polarization and Mott-Schottky curve, were measured.

The stability passivation occurred after 16h immersion in the simulated concrete pore solution. The electrochemical impedance spectroscopy presented high frequency capacitive loop and low frequency Warburg impedance, and n-type semiconductor property was found. However,  $\text{Cl}^-$  destroyed passive film. As a result, passivation curve disappeared, and two capacitive loops were observed. The donor concentration in the film increased significantly.

The corrosion protection of surface treated Al93Mg7 alloy in 3.5% NaCl containing aqueous electrolytes using films of 1,2-bis(triethoxysilyl)ethane and silane-graphene hybrids is studied. The electrochemical behavior of the alloy was studied using potentiodynamic polarization, electrochemical impedance spectroscopy (EIS) and the surface structure was investigated using scanning electron microscopy and energy-dispersive X-ray spectroscopy and X-ray photoelectron spectroscopy techniques. The surface coating was administered to the alloy by immersion of the chemically pretreated surface. A highly cross-linked film was developed of the silane film and the hydrated aluminium oxide layer.

Effect of immersion time in silane showed that optimum protection efficiency was achieved after 30 minutes. The silane film showed a high protection namely against pitting development. SEM images proved that pits develop only over unprotected surfaces. EIS data showed high protection efficiencies up to 168 hours of immersion in the chloride-containing solution. Graphene oxide was mixed with the silane solution with different ratios. The efficiency of protection increased in presence of graphene structures as the hydrophobicity of the surface increases. The surface was characterized using surface enhanced Raman spectroscopy (SERS).

SEM micrographs of Al93Mg7 surface (a, b) bare and silane coated Al93Mg7 before immersion in 3.5% NaCl, (c) bare Al93Mg7 after 24 h of immersion in 3.5% NaCl, (d) unscratched silane-coated Al93Mg7 after 24 h of immersion in 3.5% NaCl at 25°C.

Thin walled aluminium extruded tubes for heat exchangers are widely used by the automotive industry. More stringent lifetime requirements for the HVAC&R (Heat, Ventilation, Air Conditioning and Refrigeration) market necessitate improved corrosion resistance to pitting. This work investigates cathodic protection of aluminium surface modified by diffused zinc surface layer. 3000 type Al-Mn alloy multi-port extruded tubes were coated with zinc by thermal-arc spraying. The samples were afterwards heat treated at various temperatures and durations to obtain solid-state AlZn alloy diffusion layer at the surface. The Zn depth profiles obtained were characterized by glow discharge optical emission spectroscopy (GD-OES). Corrosion of the diffusion layers was subsequently determined by immersion in acidified artificial sea water solution at 25 °C, during which the open circuit potential change was recorded with respect to time. The samples were taken out at various times and their weight loss was measured. The surface microstructure and chemistry before and after corrosion were examined by scanning electron microscopy and energy-dispersive X-ray spectroscopy. Samples were also etched by argon sputtering to selected depths and subsequently characterized electrochemically. The Zn-rich layer is effective in cathodic protection against pitting. However, the layer is also susceptible to uniform self-corrosion. The well-known relationship between the corrosion potential of AlZn alloys and Zn concentration [1] was extended over a wider concentration range and related further to the corrosion rate in acidified synthetic seawater. The database thus developed is useful for optimizing the diffusion layer thickness and Zn concentration profile in the layer to minimize uniform corrosion, and therefore maximize service lifetime, without reducing the protection against pitting.

# Electrochemical properties of $\eta$ -MgZn<sub>2</sub> phase in sulfuric acid : anodizing behavior at high potential

J. Tardelli, E. Rocca\*

*Institut Jean Lamour, Université de Lorraine – CNRS, Faculté des Sciences et Techniques, 54500  
Vandoeuvre les Nancy, France.*

*\*emmanuel.rocce@univ-lorraine.fr*

The  $\eta$ -MgZn<sub>2</sub> phase is an important intermetallic phase present in some galvanized coatings on steel, but also is present as strengthening phase in many aluminum alloys belonging to the 7XXX series.

The objective of this work is to characterize the electrochemical behavior of MgZn<sub>2</sub> phase in the classical electrolyte of aluminum anodizing, H<sub>2</sub>SO<sub>4</sub> 2 M.

Firstly, bulk phase was synthesized by melting pure zinc and magnesium at 700 °C during 1 hour in a furnace under argon flux, then the sample was annealed at 400 °C during 12 hours.

As expected by the E-pH diagram of zinc and magnesium, the MgZn<sub>2</sub> phase undergoes a rapid dissolution in sulfuric acid medium at open-circuit potential. The surface analysis show a classical morphology of metallic dissolution.

Nevertheless, at the voltage of aluminium anodizing process, MgZn<sub>2</sub> phase reveal a passivation plateau, as shown in Fig. 1. The passive current density remains relatively high, around 20 mA cm<sup>-2</sup> at 10 V, but the dissolution rate of the phase is drastically reduced and we observe the formation of a thin layer of oxide on the surface.

SEM analysis and X-ray photoelectron spectroscopy allowed us to determine the overall composition of the oxide, Mg<sub>x</sub>Zn<sub>1-x</sub>O. The growth kinetic of oxide was characterized in function of voltage and anodizing time by in-situ electrochemical impedance spectroscopy measurements at high voltage. Moreover, these impedance measurements revealed the blocking behavior of the oxide layer at certain voltage and time.

# Passive Film Characterization on New Ternary Ti-Ta-Zr Alloy Surface

C. Vasilescu, S. I. Drob, S. Preda, J. M. Calderon Moreno, P. Osiceanu  
Institute of Physical Chemistry "Ilie Murgulescu" of Romanian Academy  
Spl. Independentei 202, 060031, Bucharest, Romania  
cora\_vasilescu@yahoo.com

The new Ti-15Ta-5Zr alloy was elaborated with the aim to be use as implant material; indeed, this alloy accomplishes the most necessary requirements: non-toxic elements, biphasic  $\alpha + \beta$ , stable, homogeneous microstructure (by optical, SEM and XRD techniques), a good hardness, proper mechanical properties and low Young's modulus of 42.2 GPa (from stress-strain curve)

The composition and thickness of the alloy passive film were determined by XPS from survey spectrum, high resolution spectra, respectively by sputter depth profile (Fig. 1). The alloy passive film contains  $\text{TiO}_2$  and  $\text{Ti}_2\text{O}_3$  oxides and very resistant  $\text{Ta}_2\text{O}_5$  and  $\text{ZrO}_2$  oxides with a thickness of  $8.5 \pm 1$  nm, being thicker than that of Ti and other implant alloys. By its content and thickness, this passive film confers a higher resistance to corrosion for the new Ti-15Ta-5Zr alloy.

Fig. 1 High resolution spectra for the native passive film on Ti-15Ta-5Zr alloy surface

The interactions of the new alloy with Ringer solution of different pH values (3.54; 7.49; 8.98) simulating the severe functional conditions of an implant were studied by the potentiodynamic cyclic and linear polarization and electrochemical impedance spectroscopy (EIS) methods. Also, the open circuit potentials and corresponding potential gradients were monitored for 500 immersion hours in Ringer solution.

The electrochemical measurements (Fig. 2a) attested a noble behavior of Ti-15Ta-5Zr alloy in comparison with Ti: the shift of the corrosion and passivation potentials to more electropositive values, the decrease of the passive and corrosion current densities, a better tendency to passivation, a higher polarization resistance (about 10 times higher) and lower corrosion rate (about 50 times smaller). All these facts are due to the alloying elements Ta and Zr which stabilize and reinforce the alloy passive film.

The impedance Nyquist spectra (Fig. 2b) as open arches had bigger diameters and impedance values for the alloy than for Ti, describing a more insulating, thicker passive film. Bode impedance spectra (Fig. 2c) showed linear slopes and high impedance values which confirm the superior capacitive response of the alloy. Bode phase angle spectra (Fig. 2d) displayed two phase angle which suggest a passive film with two layers: the higher phase angle corresponds to the barrier, compact, inner layer and the lower phase angle indicates the porous, outer layer. An electric equivalent circuit with two time constants was fitted.

Fig. 2 Cyclic polarization curve (a), Nyquist (b), Bode impedance (c) and Bode phase angle (d) spectra for Ti-15Ta-5Zr alloy in Ringer solution of pH = 7.49

The alloy open circuit potentials increased in time, namely, the alloy passive film thickened over time, enhancing its resistance. Because the alloy open circuit potential gradients had very low values, it is not possible to appear galvanic or local corrosion on its surface, even for long term (500 h).

# A New Dental Alloy with Improved Properties: Its Corrosion Resistance in Various Conditions Simulating Oral Cavity Environment

S. I. Drob, C. Vasilescu, J. M. Calderon Moreno, P. Osiceanu  
Institute of Physical Chemistry "Ilie Murgulescu" of Romanian Academy  
Spl. Independentei 202, 060031, Bucharest, Romania  
sidrob@chimfiz.icf.ro

A new alloy with Co-Cr base containing resistant Nb and Zr elements (Co-Cr-Nb-Mo-Zr) was synthesized; this alloy has a homogeneous microstructure (by scanning electron microscopy, SEM), favorable mechanical properties and better corrosion resistance comparing with commercial Co-Cr base alloys. X-ray diffraction (XRD) method determined the constituent phases and energy dispersive X-ray spectrum (EDX) identified the quantity of the alloying elements.

X-ray photoelectron spectroscopy (XPS) analyzed the composition of the native passive film existing on the alloy surface; this comprises protective chromium and cobalt oxides and, in addition, very resistant niobium and zirconium oxides. It is expected that this passive layer to be more compact, more insulating, and more resistant than those on the surface of the similar alloys.

The corrosion resistance of Co-Cr-Nb-Mo-Zr alloy was studied in artificial Carter-Brugirard saliva of various pH values (2.54; 7.84; 9.11) and in saliva doped with 0.05M NaF (pH = 8.21) which reproduce the real conditions from the oral cavity. The normal pH is about 7.4; after a meal, the pH can reach 3 - 4 value and in the case of infections or inflammations, a value of about 8 - 9.

Three electrochemical methods were used: cyclic potentiodynamic polarization to estimate the main electrochemical parameters (corrosion -  $E_{\text{corr}}$  and passivation -  $E_p$  potentials, tendency to passivation -  $|E_{\text{corr}} - E_p|$ , and passive current density -  $i_p$ ); linear polarization method, by Tafel representations supplied the main corrosion parameters (corrosion current density -  $i_{\text{corr}}$ , corrosion rate -  $V_{\text{corr}}$ , polarization resistance -  $R_p$  and ion release rate); electrochemical impedance spectroscopy (EIS) that furnished Nyquist and Bode spectra and electrical parameters of the electric equivalent circuit describing the physical phenomena at the interface between alloy and artificial Carter-Brugirard saliva. The cyclic potentiodynamic curves evinced the alloy self-passivation characterized by the more favorable, more electropositive corrosion and passivation potentials, better tendency to passivation and lower passive current densities referring to the commercial Co-Cr alloy (Table 1). Corrosion current densities, corrosion rates and ion release rates had low values placed under the permitted limits ( $V_{\text{corr}}$  - limit of 0.25  $\mu\text{m/Y}$ ). Corrosion resistance had very high values, fact that denotes a very resistant passive film (Table 1).

Table 1. Main electrochemical and corrosion parameters for Co-Cr-Nb-Mo-Zr alloy in Carter-Brugirard saliva

Parameter	Saliva pH = 2.54		Saliva pH = 7.84		Saliva pH = 9.11		Saliva + 0.05M NaF pH = 8.21	
	Commercial alloy	New alloy	Commercial alloy	New alloy	Commercial alloy	New alloy	Commercial alloy	New alloy
$E_{\text{corr}}$ (mV)	-410	-380	-353	-270	-413	-370	-438	-406
$E_p$ (mV)	-200	-300	-250	-220	-200	-300	-200	-300
$ E_{\text{corr}} - E_p $ (mV)	212	80	153	50	213	70	238	106
$i_p$ ( $\mu\text{A}/\text{cm}^2$ )	3.9	3.5	1.8	1.6	3.7	3.5	4.5	4.2
$i_{\text{corr}}$ ( $\mu\text{A}/\text{cm}^2$ )	0.022	0.018	0.013	0.011	0.015	0.014	0.038	0.031
$V_{\text{corr}}$ ( $\mu\text{m/Y}$ )	0.249	0.14	0.148	0.0858	0.167	0.109	0.431	0.242
$R_p$ ( $\text{k}\Omega \cdot \text{cm}^2$ )	0.589	251.9	1.25	751.4	1.23	264.3	0.546	216.5
Ion release rate ( $\text{nm}/\text{cm}^2$ )	25.29	14.20	15.04	8.70	16.96	11.95	43.79	24.56

Electrochemical impedance spectroscopy indicated an insulating film depicted by high impedance and phase angle values, proving a more capacitive, resistant passive film on the alloy surface, comparing with the commercial Co-Cr alloys.

# Comparative analysis of the Anodic Dissolution of Iron at low and high over potentials

M.A. Pletnev

*Kalashnikov Izhevsk State Technical University, 7 Studencheskaya street  
426069 Izhevsk, Russia  
[pletnev@list.ru](mailto:pletnev@list.ru)*

Reaction of anodic dissolution of hydrophilic metals in the low-voltage surge follows:

When N – nucleophilic species dissolved in the electrolyte solution (anions or water molecules).

Crystal of iron is anodically polarized and has the charge ( $n^+$ ). The preceding stage represents the partial destruction of the crystal lattice with the formation of semi-crystalline state of  $\text{Fe}_k$ . The next stage is getting out of the metal atom from the kink and the transition into the adsorbed state  $\text{Fe}_{\text{ads}}(\text{I})$ . Speed limiting stage (an act of anodic depolarization of the iron as a cooperative electronic system with a force too low polarization of the Fermi level) is entering into the surface layer of electrolyte (interaction with water and other nucleophilic components of the electrolyte N) leaves the surface of the metal ion (II - III). The overvoltage of this process can be identified with the surge stage of the discharge-ionization.

In the acid solutions the binding energies are much larger and the O...O distances are shorter compared to pure water. Consequently, with increasing pH the activation energy of the iron ions hydration (III) to be reduced, while the dissolution rate to be increased. Such data were obtained in most articles.

Bandwidth limiting anodic current does not depend on pH, nature of the anion, but depends on the concentration of anions. To interpret the experimental data on the limiting currents of anodic dissolution a phenomenological approach is proposed based on the concept of soliton. Bandwidth limiting anodic current does not depend on pH, nature of the anion, but depends on the concentration of anions. To interpret the experimental data on the limiting currents of anodic dissolution proposed a phenomenological approach based on the concept of solitons as the dissolution of the concentration waves moving parallel to the flat surface of low index faces.

Comparative analysis of the anodic dissolution of iron at low and high potentials has showed that these processes have different mechanisms. Models anodic dissolution of iron interpreted in the light of the notion of co-operative nature of the electron subsystem of the metal. Assumed that the mechanism of anodic ionization of iron at low overvoltages is ions desorption from the surface, which requires "embed" it in the electrolyte layer near the electrode. To interpret the experimental data on the limiting currents of anodic dissolution a phenomenological approach is proposed based on the concept of solitons.

# Local Electrochemical Study on the Effect of Residual Stresses on Localized Corrosion Susceptibility of Type 316 Stainless Steels

Lin Niu, Xiaoping Han, Yu Liu, Weiwei Zhang, Rui Ma, Shuai Li, Tong Li

*E-mail: lniu@sdu.edu.cn*

One of the major obstacles for accurately determining the corrosion resistance of metallic alloys is the lack of knowledges concerning the effect of correlative parameters (especially mechanical ones) on the initiation and propagation processes of localized corrosion [1]. Therefore, it is of great significance to pursue a deeper understanding of corrosion mechanisms of metals with the development of a multidisciplinary approach involving material, chemical, physical and mechanical sciences. To study the kinetics of heterogeneous electrochemical processes in localized corrosion, the local electrochemical probes with advantages of in-situ measurement and high spatial resolution have attracted apparent attentions [2].

In this work, the combinations of conventional electrochemical methods (e.g. potentiodynamic polarization curves) and local probe approaches based on local electrochemical measurements such as scanning electrochemical microscope (SECM) and scanning vibrating electrode technique (SVET) have been devoted to study at the micro-scale the correlation between surface residual stresses (especially the local stress gradients inside the tested area) and the electrochemical behavior and localized corrosion susceptibility of type 316 stainless steels in chloride-containing solution. The objective of the present study is to further clarify the “mechano-chemical interaction” in relevant ‘materials, mechanics and environments’ system, and to investigate the spatial distribution of the electrochemical reactions and finally determine the corrosion rate of the metal.

# Assessing and Predicting Concurrent Uniform Corrosion of Aluminum Alloys as a Function of pH, Temperature, Time, and [Cl<sup>-</sup>]

I-Wen Huang, Rudolph G. Buchheit  
*Fontana Corrosion Center, The Ohio State University*  
*2041 N. College Rd. Columbus, OH 43210*  
*huang.697@osu.edu*

High strength aluminum alloys are known to be particularly susceptible to localized corrosion induced by heterogeneous intermetallics, but the ability to quantitatively assess uniform corrosion along with pitting has become a major challenge for pit growth prediction. The pit depth measurement is shown to be affected by reference surface changing due to uniform corrosion as well as pit agglomeration. Therefore, the ability to measure pit depths and uniform corrosion simultaneously by profilometric methods to compensate for the reference surface recession has become a critical correction needed in aqueous conditions.

In this work, pitting corrosion and uniform dissolution of aluminum alloys 2024-T3, 7075-T6 and 6061-T6 were characterized quantitatively using optical profilometry (OP) after free corrosion exposures in 0.01 to 1.0 M NaCl solutions as a function of pH, temperature and exposure time. Uniform dissolution was estimated by carefully measuring the step height between the masked surface and the exposed surface along with pitting information. Results showing that a temperature and pH has a complex impact on Al alloy corrosion behavior. Under neutral and alkaline conditions, the corrosion rate of all three alloys at 80°C had the lowest corrosion rate, appearing to be related to the fact that slowed oxygen reduction reaction. This result is supported by the electrochemical experiment where cathodic limiting current was slowed by the reduced oxygen solubility at elevated temperature. Electrochemical impedance spectroscopy (EIS) result also showed elevated polarization resistance at high temperature from  $10^4$  to  $10^9$  (ohm·cm<sup>2</sup>). It was also found that a passive film formation and breakdown intermittently during a long term immersion, which was not observable in short term electrochemical tests, protecting the surface in high temperature conditions. Corrosion product and passive film analysis was performed by energy-dispersive X-ray spectroscopy (EDS) and electron diffraction. Samples prepared by focused ion beam (FIB) were examined to identify the composition and microstructure of corrosion product in both low and high temperatures. Moreover, a statistical corrosion model was established according to all measurement acquired through immersion tests. In general, Al alloy 6061 has slower uniform corrosion rate than 2024 and 7075. In order to validate the proposed pit morphology influenced by uniform corrosion, long term sample immersion and B117 salt spray chamber tests were also employed. Maximum pit depth was carefully found and a detailed profile scan was conducted by OP. This pit profile obtained unveils the altering pit geometry with uniform corrosion.

In addition, artificial neural network (ANN) modeling was utilized as a powerful statistic tool to recognize corrosion pattern in different environment and being able to generate predictions based on the input data. A successful prediction of uniform corrosion was given with linear regression value approximately 0.94 for AA2024 and AA7075 alloys. Aforementioned uniform corrosion modification to pit depth was found to be phenomenal in certain environmental conditions. In this poster, details of the experimental method and the results will be presented and the implication of these results on corrosion damage accumulation modeling will be addressed.

# Influence of Crevice Thickness to Corrosion Behavior of API X80 Steel under Disbonded Coating in Acid Soil Environment

Bo Zhao, Zhiyong Liu, Cuiwei Du, Xiaogang Li, Binan Shou, Tong Xu  
China Special Equipment Inspection And Research Institute  
2 Building, Xiyuan, Hepingjie, Chaoyang District Beijing, P.R. China  
Zhaobo19840626@163.com

In this work, an experimental device of disbonded coating model in yingtian soil simulation was prepared, and the corrosion behavior of X80 steel in it was studied by anodic polarization curves, electrochemical impedance spectroscopy (EIS) and scanning electron microscope (SEM). As the results showed, anode region of X80 steel would appear “passivation” behavior when the crevice thickness was about 35  $\mu\text{m}$ , but the anodic current density increased and anode active dissolution tendency enhanced with the crevice thickness becoming larger.

According to the result of EIS, the inductive loop appeared in low frequency area, which indicated that adsorption reaction appeared on electrode surface. The fitting equivalent circuit showed that the solution resistance ( $R_s$ ) of electrode reaction decreased monotonously with crevice thickness becoming larger, and the charge transfer resistance ( $R_{ct}$ ) achieved the minimum and maximum values at the thickness were 150  $\mu\text{m}$  and 400  $\mu\text{m}$  after its early decreasing rapidly.

The microstructure showed that, the corrosion product present the structure of regular sheets on X80 steel surface, but it disappeared and due to porosity with the thickness becoming larger. After removal corrosion product, it could be found that the corrosion of the sample surface was the most serious in the crevice thickness of 100 $\mu\text{m}$ , and the pitting appeared at this situation.

Fig1. X80 steel with different disbonded crevice thickness of (a)potentiodynamic polarization, (b)EIS .

# Electrochemical Performance of Oxygen Evolving Anodes in Sulphate Electrolyte for Copper Electrowinning

Wenting Xu<sup>1</sup>, Geir Martin Haarberg<sup>1</sup>, Svein Sunde<sup>1</sup>

<sup>1</sup>Department of Materials Science and Engineering, Norwegian University of Science and Technology

wenting.xu@ntnu.no

In industrial copper electrowinning, the oxygen evolution reaction (OER) is the main anode reaction. Compared with conventional lead-based anodes, dimensionally stable anodes (DSA) can decrease the OER overpotential and increase the energy efficiency during electrolysis since DSA have high catalytic activity and stability against corrosion. Application of DSA offers a commercially viable and environmentally friendly alternative in copper electrowinning [1].

Many researchers have studied the characteristics of DSA in order to find the most suitable DSA for oxygen evolution in copper sulphate electrolyte [2]. In addition, electrochemical stability in sulphate electrolytes, mechanical stability and structural integrity are also essentially required for those anodes in copper electrowinning. In this paper, industrial DSAs consisting of mixed metal oxide coatings on titanium including tantalum oxide ( $\text{Ta}_2\text{O}_5$ ), iridium oxide ( $\text{IrO}_2$ ), and ruthenium oxide ( $\text{RuO}_2$ ) were investigated in sulphate electrolyte at 60 °C in the context of copper electrowinning. X-ray diffraction (XRD) and scanning electron microscopy (SEM) were employed to examine the crystal structure, composition of the catalytic layer and its surface morphology. The electrochemical properties of the different catalytic layer were studied by cyclic voltammetry (CV), as shown in Fig.1. The behaviour of surface charges for these different coatings have been evaluated by CV tests under varying scan rates. Overvoltage of oxygen evolution for each DSA has been determined by steady state polarization analysis, as shown in Fig.2. The paper will relate the influence of composition on performance and durability of these DSA electrodes under industrially relevant operating conditions.

Fig.1. Cyclic voltammetry of three anodes scanned at 50 mV/s at 60 °C in copper sulphate electrolyte (1.2 mol/L  $\text{Cu}^{2+}$  and 1.8 mol/L  $\text{H}^+$ )

\*E-mail: [kcho@ntu.edu.tw](mailto:kcho@ntu.edu.tw)

Recently, transition metal compounds have been successfully reported as the electro-catalytic counter electrodes (CE) in dye-sensitized solar cells (DSSCs). Generally, transition metal compounds provide good electro-catalytic ability, high conductivity, large effective surface area, and good stability for the regeneration of the redox species (*e.g.*,  $\text{I}^-/\text{I}_3^-$ ); therefore, they show a great potential to replace the traditional noble metal, platinum (Pt). Among those transition metal compounds,  $\text{FeSe}_2$  film was reported as an earth abundant, a highly electro-catalytic, and a thermodynamically stable material toward the reduction of  $\text{I}^-/\text{I}_3^-$ . However, the reported  $\text{FeSe}_2$  film often lacks of low-dimensional structures, and thus the fill factor (*FF*) of pertinent DSSC was limited.

In this study, we aim to synthesize a  $\text{FeSe}_2$  nanorod array on a flexible Fe foil via a simple anodization method followed by a post-selenization thermal treatment. From the X-ray diffraction pattern (XRD) analysis, the  $\text{FeSe}_2$  nanorod array shows a ferroselite  $\text{FeSe}_2$  crystalline with the orthorhombic structure (JCPDS No. 65-2570). From field-emission scanning electron microscopy (FE-SEM) image shown in Fig. 1(a), it is observed that the  $\text{FeSe}_2$  nanorod array was growth perpendicularly onto the Fe foil, and they possessed a one-dimensional (1D) structure with an average diameter about 100 nm and an average length about 1  $\mu\text{m}$ . This 1D  $\text{FeSe}_2$  nanorod array was believed to benefit the electron transport capability of a CE, resulting better electro-catalytic ability and the cell efficiency. From the cyclic voltammetry (CV) analysis, the cathodic peak current density of  $\text{FeSe}_2$  nanorod array shows a value of  $1.12 \text{ mA cm}^{-2}$ , which is very close to that of the Pt film ( $1.43 \text{ mA cm}^{-2}$ ); therefore, the  $\text{FeSe}_2$  nanorod array was considered to have the comparable electro-catalytic ability to that of Pt. In Fig. 1(b), the photocurrent density–voltage curves of the DSSCs with Pt and  $\text{FeSe}_2$  nanorod array films as the CEs gave cell efficiencies ( $\eta$ ) of 7.80% and 7.59%, respectively. It can be said that the obtained  $\text{FeSe}_2$  nanorod array is a highly potential electro-catalytic material to replace Pt.

Fig. 1 (a) FE-SEM image of  $\text{FeSe}_2$  nanorods and (b) photocurrent density–voltage curves of the DSSCs with Pt and  $\text{FeSe}_2$  films as the CEs.

# Investigation of the Structure of Fe–N–C Complexes for Oxygen Reduction Reactions

Dangsheng Su

Searching for non-precious metal-based catalyst is an important research topic for a realistic application of fuel cell technology. Transition metal-based compounds or even metal-free catalysts have been reported to be active in oxygen reduction reactions (ORR). The performance of such non-precious metal catalysts still needs further optimization for replacing Pt-based catalysts.

In acidic medium, Fe/N co-modified carbon electrocatalysts have attracted great attention due to their high activity and stability in oxygen reduction reaction (ORR). Compared to iron-free N-doped carbon electrocatalysts, Fe/N-modified electrocatalysts show four-electron selectivity with better activity. This is believed relevant to the unique Fe–N complexes. However, the Fe–N structure remains an issue of discussion. We used *o,m,p*-phenylenediamine as nitrogen precursors to tailor the Fe–N structures in heterogeneous electrocatalysts which contain FeS and Fe<sub>3</sub>C phases. The electro- catalysts have been operated for 5000 cycles with a small 39 mV shift in half-wave potential. By combining advanced electron microscopy and Mossbauer spectroscopy, we have identified the electrocatalytically active Fe–N<sub>6</sub> complexes (FeN<sub>6</sub>, [Fe<sup>III</sup> (porphyrin)(pyridine)<sub>2</sub>]). The identification of the FeN<sub>6</sub> structure as a possible active site for ORR will pave the way towards new advanced Fe–N based electrocatalysts.

In alkaline medium, it is reported that both metal-free (for instance, N-doped carbon) and non-precious metal-based catalysts (for instance transition metals) are active in ORR. We are making a systematic study on what really catalyzes ORR in nitrogen-doped nanocarbon and Fe/N/C electrocatalysts. The new findings will be presented in this talk.

# Nitride-Stabilized Tungsten Carbide Electrocatalysts for Hydrogen Evolution Reaction

Wei-Fu Chen, Kotaro Sasaki, Jonathan M. Schneider, Chiu-Hui Wang, James T. Muckerman, Etsuko Fujita

Chemistry Department, Brookhaven National Laboratory  
PO Box 5000 Upton, NY 11973-5000 USA  
wfchen@bnl.gov

Alternative materials to platinum-based catalysts are required to sustainably produce hydrogen from water at low overpotentials. Progress has been made in utilizing tungsten carbide-based catalysts, however, their performance is currently limited by the density and reactivity of active sites, and insufficient stability in acidic electrolytes. Inspiration for designing such a material can be found in hydrotreating catalysts.<sup>[1]</sup> Molybdenum carbides and tungsten carbides have been investigated most extensively as catalysts or catalyst supports for the HER.<sup>[2]</sup> To make carbides better HER catalysts, nanostructuring the surface to increase the number of reactive facets is an effective approach. The catalytic activity of metal carbides can be further modified by the incorporation of nitrogen. We have reported that the incorporation of nitrogen in a NiMo alloy enhances its corrosion resistance.<sup>[3]</sup> Interestingly, pyrolysis of nitrogen-rich polydiaminopyridine and  $\text{H}_2\text{WO}_4$  in the presence of Fe can produce the nitride-rich WC-WN nanocomposite,<sup>[4]</sup> however its HER activity was limited by the nitride-rich surface.

In this study, attempts to synthesize graphene-supported tungsten carbide and nitride nanocomposites by using aniline as the reactive nitrogen source lead to the formation of an active, durable electrocatalyst (Fig. 1) for the HER in acidic environments.<sup>[5]</sup> By using in situ solid-state approach, we have successfully prepared  $\text{W}_2\text{C}$ -WN nanocomposites on graphene nanoplatelets without using gaseous carbon or nitrogen sources. Incorporation of the  $\text{W}_2\text{C}$ -WN nanoparticles on GnP brings about a significant enhancement in the HER kinetics (Fig. 2), and faster electron transport due to the remarkable reduction in charge transfer resistance. The optimum carbonitriding and unique  $\text{W}_2\text{C}$ /WN nanostructures evidenced by HRTEM, XRD, X-ray absorption spectroscopy as well as electrochemical behavior will be discussed at the meeting.

**Fig. 1** The synthesis of graphene nanoplatelet-supported  $\text{W}_2\text{C}$  and WN nanoparticles from ammonium paratungstate, aniline and graphene nanoplatelets. Dark grey balls: W, blue balls: N, black balls: C, and red balls: oxygen.

# Gold-promoted structurally ordered intermetallic palladium cobalt nanoparticles for the oxygen reduction reaction

Kotaro Sasaki<sup>1</sup>, Kurian A. Kuttiyiel<sup>1</sup>, Dong Su<sup>2</sup>, Lijun Wu<sup>3</sup>, Yimei Zhu<sup>3</sup>, Radoslav R. Adzic<sup>1</sup>  
<sup>1</sup>Chemistry Department, <sup>2</sup>Center for Functional Nanomaterials, <sup>3</sup>Department of Condensed Matter  
Physics and Materials Science, Brookhaven National Laboratory, Upton, New York 11973, USA.  
ksasaki@bnl.gov

The search for new materials for the oxygen reduction reaction (ORR) has been challenging since the ORR is a sluggish reaction and requires high Pt content; this drawback still hampers the large scale applications of electrochemical conversion and storage devices, such as fuel cells, Li-air batteries, and electrolyzers. Key strategies to reduce Pt contents involve alloying Pt with other transition metals<sup>1</sup>, de-alloying non-precious metals to obtain a Pt rich shell<sup>2</sup> and core-shell-structured nanoparticles<sup>3</sup>. These approaches, to some degree, increase Pt utilization, but cannot fully solve the problem of Pt dependence. On the other hand, the study of ORR on Pd-based catalysts has received less attention than on Pt due to the lower activity and stability of the former<sup>4</sup>. Previous studies have mainly been pursued on the Pd alloy catalysts with various shapes and structures, and little experimental studies have been focused on structurally ordered intermetallic Pd-based nanocatalysts. However, using certain material composition and structure, ordered intermetallic phases can be obtained at nanometre ranges.

In the present paper, we address this challenge by demonstrating a simple method to synthesize core-shell-structured PdCo nanoparticles that can be further transformed into ordered intermetallic phases by addition of Au atoms and subsequent annealing<sup>5</sup>. The discovery of unusual ordering of PdCo atoms ( $3\times$  (times) and  $2\times$ ) along the [111] direction in the AuPdCo nanoparticles with twin boundaries and with stable {111}, {110} and {100} facets is revealed using high-resolution transmission electron microscope (HRTEM) and scanning transmission electron microscope (STEM) coupled with electron energy-loss spectroscopy (EELS) and electron diffraction patterns (EDPs). To our knowledge, no prior evidence of such intermetallic phases in nanoparticles of PdCo alloy has been reported. These structurally ordered intermetallic AuPdCo nanoparticles tend to behave similar to Pt catalyst for ORR, but more interestingly have much better stability than Pt in alkaline media. Furthermore, microscopic analyses of the catalyst show that atomic ordering of the nanoparticles can significantly affect the catalytic activity. The increased activity and durability of the catalyst is accredited to multiple facets and the structural ordering observed in the nanoparticles. We have established a simple and cost effective methodology to synthesize structurally ordered intermetallic PdCo nanoparticles, and it is believed that this approach may offer numerous possibilities in tailoring other transition metal intermetallics for various energy conversion and storage applications.

Metallophthalocyanines and metalloporphyrins are well known electrocatalysts for the reduction of O<sub>2</sub> (ORR) and have been extensively investigated with the aim of a better understanding of the ORR at modified electrodes and with the final scope of replacing Pt in fuel cells. Inorganic catalysts mimicking the structure of active redox centers of redox enzymes are taking place. For example Cho et al. reported higher electrocatalytic activity than Pt/C catalyst for a Fe-phthalocyanine with an axial ligand anchored on single walled carbon nanotubes that mimics the active site of *cytochrome c* oxidase [1]. Fundamental studies of MN macrocyclic complexes adsorbed on carbon nanotubes (CNTs) and on pyridine modified CNTs as catalysts for the ORR are missing. Preliminary studies in basic media show that when MN macrocyclic complexes are adsorbed at CNTs (single walled and double walled) modified electrodes an increment of almost two orders of magnitude of catalytic activity expressed as log *i* at constant potential is observed [2,3]. The reaction mechanism deduced from Tafel slopes analysis appears to be the same among the MN4 complexes adsorbed and non-adsorbed on CNT, suggesting that the CNTs support does not interfere with the reaction mechanism. An increased electroactive area and therefore an increased amount of active sites and an increment of the formal potential of the catalyst seem to be the cause of this increment. The results show the same volcano trend reported before where the activity increases as the formal potential of the metal catalyst redox center is shifted to more positive values [4]. When CNTs are modified with 4-aminopyridine aryl diazonium salts and then with axially ligated phthalocyanines even higher activities are observed but volcano correlations are distorted by the effect of the axial ligand.

# On The Effects of Bromide Adsorption on the Rates of Redox Reactions

Adriel J.J. Jebaraj, Nicholas Georgescu and Daniel A. Scherson  
Department of Chemistry, Case Western Reserve University  
Cleveland, OH 44106-7078  
[dxs16@case.edu](mailto:dxs16@case.edu)

A method has been developed and implemented that allows correlations to be established between the rates of a redox reaction on the disk of a Pt rotating ring-disk electrode, the coverage of bromide,  $\theta_{\text{Br}^-}$  and the applied potential,  $E$ . Illustrations are provided for the effects of adsorbed bromide on Pt electrodes which enhances in one case the reduction of iron(III) hexaaquo,  $[\text{Fe}(\text{H}_2\text{O})_6]^{3+}$ , and depresses the reduction of hydrogen peroxide in 0.1 M  $\text{HClO}_4$  solutions. These experiments were performed in  $\text{Br}^-$ -containing solutions at concentrations in the  $\mu\text{M}$  range. The experimental strategy involves application of a potential step from a value at which there is no  $\text{Br}^-$  adsorption,  $E_0$ , to a more positive potential at which  $\text{Br}^-$  undergoes adsorption under strict diffusion control,  $E_{\text{ads}}$ , over periods on the order of seconds. Evidence that the redox reactions do not interfere with  $\text{Br}^-$  adsorption process was obtained from in situ differential reflectance measurements performed in the absence and in the presence of the redox active species yielded virtually identical results. Correlations between  $\theta_{\text{Br}^-}$  and time for various  $E_{\text{ads}}$  were obtained from the analysis of chronoamperometric curves recorded in solutions devoid of the redox reactant from the temporal response of the Pt ring shielding currents for  $\text{Br}^-$  oxidation.<sup>1</sup> The information derived from these measurements was then used to establish the dependence of the disk current due to the redox reaction and the amount of solution phase  $\text{H}_2\text{O}_2$  produced, as measured by the ring, on both  $E_{\text{ads}}$  and  $\theta_{\text{Br}^-}$ . Shown in Panel A, Fig. 1, are plots of the peroxide reduction currents,  $i_{\text{disk}}$ , as a function of  $E_{\text{ads}}$  recorded in a 1 mM  $\text{H}_2\text{O}_2$  solution containing 10  $\mu\text{M}$  KBr in 0.1 M  $\text{HClO}_4$  for the Pt disk of a Pt|Pt RRDE at  $\omega = 200$  rpm, based on chronoamperometric data acquired following a potential step from  $E_0 = 0.03$  V to various values of  $E_{\text{ads}}$ . Corresponding plots of  $i_{\text{disk}}$  vs  $\theta_{\text{Br}^-}$  for various values of  $E_{\text{ads}}$  as indicated in the legend are given in Panel B in the same figure. These data are currently under analysis to extract kinetic parameters as a function of both coverage and potential.

**Acknowledgements.** This work was supported by a grant from the National Science Foundation.

Polymer electrolyte membrane fuel cells (PEMFC) provide a promising link in the future sustainable energy cycle. However, the major disadvantages today are the high capital cost [1] and insufficient stability [2] of the applied Pt nanoparticle electrocatalysts.

In this work, highly porous transition metal nanoparticles (Pt, Ni) were electrochemically deposited on a glassy carbon substrate using a dual pulse technique. These NP's could be synthesized with high selectivity and the morphology of the nanoclusters was tuned by changing electrolyte composition and deposition parameters. Both morphological properties (particle size, porosity, surface roughness, high index planes, etc.) and ORR reduction activity were elucidated using a combination of surface analysis techniques (HAADF-STEM and Electron tomography) and electrochemical techniques (linear and cyclic voltammetry).

**Figure 1: Activity decrease related to the porosity relapse after subsequent potential cycling.**

The as prepared Pt nanoparticles with diameter ranging between 40-60 nm revealed nanometer scale artifacts and an increased activity towards ORR. A contraction of the Pt-Pt bond distance and the consequential changes in electronic properties could explain the elevated activity. However, upon subsequent potential cycling (600 cycles between 0,05 V and 1,4 V vs RHE) the porosity of the particles appeared to decrease from 12% to only 2%. In accordance with this relapse in porosity also the ORR activity appeared to decrease as indicated by a 100 mV shift in the linear sweep voltammograms.

The application of this described methodology as a first step in the synthesis of core-shell nanoparticles through galvanic displacement appeared a valid strategy in this work with respect to their ORR activity and stability. We have previously shown the potential catalytic enhancement of comparable core-shell NP's prepared by galvanic displacement towards ORR [3].

Alloy-based electrocatalysts are currently being intensively studied as electrode catalysts for fuel cells. The alloys are believed to operate either via a ligand effect or via a bifunctional mechanism, which may apply either separately or simultaneously. The ligand effect is connected with capability of tuning the electronic structure of an alloy by controlling its composition; the bifunctional mechanism implies a work-sharing between different surface atoms which host different adsorbed reactants or reaction intermediates. The traditional approach in the optimization of alloy catalysts considers the surface structure to be static, *i.e.*

the active sites are created during the catalyst synthesis and do not change over the course of the electrocatalytic reaction. This assumption has been challenged by both theoretical<sup>1</sup> and experimental studies,<sup>2, 3</sup> describing selective, reaction-triggered surface segregation of the alloy.

The presented work probes the dynamic evolution of the catalyst surface structure of a model bifunctional catalyst based on Pt and Ru. *In-situ* X-ray absorption spectroscopy (XAS) both in XANES and EXAFS modes is used to monitor the time-evolution of the Pt<sub>2</sub>Ru surface structure during formate oxidation. The formate oxidation process proceeds via an adsorbed CO intermediate affects the local environment of both alloy components. Ru, which is originally present at the surface in a form of surface oxide is apparently partially reduced when CO replaces the oxygen-containing species on Ru (see Fig. 1). CO for oxygen replacement conforms to first order kinetics and matches the exponential decay of the observed formate oxidation current (see Fig. 1b). The apparent reduction of surface-confined Ru results in a more homogeneous distribution of Ru in the catalyst particles; the local chemical composition starts to approach the average chemical composition obtained in chemical analyses. The observed experimental trends are analysed with the help of density functional theory (DFT) calculations and the most likely surface structures and active sites are identified.

**Figure 1** Time dependence of the number of oxygen atoms and CO groups coordinating an average Ru atom in a nano-particulate Pt<sub>2</sub>Ru catalyst (a) during potentiostatic oxidation of 0.2M formate in 0.1M perchloric acid at 0.4 V vs. RHE. The corresponding chronoamperometric signal is shown in panel (b).

# Performance of PEMFC Half Cells Prepared Using Hierarchical Microporous-Macroporous Carbon Supported Pt-Catalyst

Silver Sepp, Jaak Nerut, Kersti Vaarmets, Indrek Tallo, Enn Lust  
*Institute of Chemistry, University of Tartu*  
*14a Ravila Str. 50411, Tartu, Estonia*  
*e-mail silver.sepp@ut.ee*

Hierarchical Microporous-Macroporous Carbons (HMMPC) with different physical and electrochemical properties have been synthesized. Their pore size distribution and well defined hierarchical porous structure makes them interesting object to be used as a catalyst support in polymer electrolyte membrane fuel cells (PEMFC) [1, 2]. It has been shown, that HMMPCs are suitable materials to be used as catalyst support [3]. Studies have proven that electrodes prepared using HMMPCs are much more active towards oxygen electroreduction than commercially used carbon materials [2, 3]. Pt-nanoparticles were deposited onto studied carbon materials using  $\text{NaBH}_4$  reduction method. Fuel cell half-cells have been prepared with Pt-activated HMMPCs using catalyst coated membrane method. The structure of studied materials has been characterized using XRD, SEM and gas adsorption/desorption measurements. The electrochemical active surface area was estimated from  $\text{H}_2$  adsorption method in the form of cyclic voltammograms and the half-cell resistances were investigated using electrochemical impedance spectroscopy. Polarization curves have been measured for materials prepared applying various synthesis conditions and compared with data for commercial Vulcan XC72-based catalyst materials. It was found that synthesized carbon supports are suitable for PEMFC half-cell application due to their high catalytic activity and stability.

The interface between metallic electrodes and the ionic pairs present in room temperature ionic liquids (RTILs) is still far from being well understood [1,2]. Single crystal electrodes represent the most convenient type of surface structured electrodes for studying the impact of RTIL ions adsorption in relevant electrocatalytic reactions, such as surface sensitive electrochemical CO<sub>2</sub> reduction. We propose here, for the first time, the formation of a stable complex formed between CO<sub>2</sub> and the imidazolium based cation [C<sub>2</sub>mim<sup>+</sup>] as a result of a radical-radical coupling reaction, in which both reactants have been previously electrochemically reduced. The formation of such a stable complex (C<sub>2</sub>mim-CO<sub>2</sub><sup>-</sup>) blocks CO<sub>2</sub> reduction after a single electron transfer and inhibits CO<sub>2</sub> and imidazolium dimerization reactions. However, the electrochemical reduction of CO<sub>2</sub> under those conditions provokes the electrochemical cathodic degradation of the imidazolium based RTIL. This important limitation in CO<sub>2</sub> recycling by direct electrochemical reduction is overcome by adding a strong acid, [H<sup>+</sup>][NTf<sub>2</sub><sup>-</sup>], in solution. Then, protons become preferentially adsorbed on the electrode surface by displacing the imidazolium cations and inhibiting their electrochemical reduction. As it is shown in Figure 1, this fact allows the surface sensitive electro-synthesis of HCOOH from CO<sub>2</sub> reduction in [C<sub>2</sub>mim<sup>+</sup>][NTf<sub>2</sub><sup>-</sup>] [3], being Pt(110) identified here as the most active among the basal plane electrodes studied.

Figure 1. Electrochemical CO<sub>2</sub> reduction in two different Pt-RTIL interfaces.

# Effects from modifying carbon nanofiber supports on metal nanoparticle catalyzed CO<sub>2</sub> reduction

Ida Hjorth, Navaneethan Muthuswamy, De Chen  
Norwegian University of Technology and Science  
Trondheim, Norway  
ida.hjorth@ntnu.no

Solar energy can be harnessed indirectly to convert CO<sub>2</sub> in an artificial photosynthesis process. The electricity produced by photo-voltaic systems, wind turbines or hydro-power stations, can be used to run electrolyzers, where CO<sub>2</sub> is electrochemically reduced into carbon monoxide, methane or alcohols. There are currently no stable, efficient and selective catalysts for the process, and therefore new catalytic materials must be designed such that these problems can be solved.

A promising strategy is to include catalyst nanoparticles in the design, since a larger fraction of the surface atoms will be at an edge or a corner, which may increase the reactivity. In addition, they provide a larger surface area which will increase the activity of the catalyst. These catalyst particles can be dispersed on electrically conductive carbon nanofibers. It is shown that modification of the carbon surface by removal of oxygen or doping, can improve the dispersion of metal nanoparticles[1]. In addition, support effects can be tuned to accept or donate electrons to the particle[2]. While these materials are interesting materials for catalysis, they have not received much attention for the CO<sub>2</sub> reduction. Due to their high potential, carbon nanofiber supported metal nanoparticles should be studied also for this reaction.

Cu is a natural starting point, as it is the most active metal for hydrocarbon production[3]. In this project, different types of carbon nanofibers are doped or oxidized, and oxygen groups are removed from the surface. Cu nanoparticles are deposited on the fibers, by colloid deposition, impregnation and the Pechini method. The copper is also alloyed with zinc. The final catalyst powers are tested for electrochemical CO<sub>2</sub> reduction in a CO<sub>2</sub> saturated aqueous KHCO<sub>3</sub> solution, where the selectivity, activity and stability of the catalyst is studied.

Preliminary results show that copper colloids deposited on carbon nanotubes where the oxygen groups are removed are more active and selective towards methane formation, compared to colloids deposited on tubes that are oxidized and decorated with a comparable copper loading and particle size distribution.

adriano.gomes@chem.gu.se*

The electrosynthesis of sodium chlorate is one of the most important industrial practices. In the process the main cathodic reaction is water reduction. The electrolyte is composed of sodium chlorate and sodium chloride with a total salt concentration of about 8.0 moles L<sup>-1</sup>. The process optimum temperature is 80 °C and improving the cathodic current efficiency for hydrogen evolution under such conditions is a challenge. The reaction occurs at mild steel electrodes, which are not selective for hydrogen evolution and sodium dichromate is added to the electrolyte to avoid side reactions [1, 2]. However, the overpotential for water reduction is still considered high, which leaves room for improvements [3].

One question to be answered is: how does the salt concentration affects the electrochemical water reduction kinetics? Monte-Carlo simulations have shown that the water activity decreases at increasing salt concentration and the extent of such decrease is salt specific (Figure 1a). Experiments have also demonstrated that the water reduction kinetics are salt concentration dependent (Figure 1b). The aim of this study is to investigate to what extent these effects are connected to each other, including also the temperature dependence. Discussions will be based on reaction kinetics, mechanisms and the structure of the electrode-electrolyte interface.

**Figure 1** – (a) Water activity as a function of salt concentration for NaClO<sub>4</sub> and NaClO<sub>3</sub>. (b) Experimental (symbols) and simulated kinetic currents (dotted lines) for water reduction in electrolytes containing NaClO<sub>4</sub> at 0.2 and 4.0 mol L<sup>-1</sup>.

In order to reduce the Pt loading at the cathode of proton exchange membrane fuel cells (PEMFCs), more active and stable catalysts are needed to drive the oxygen reduction reaction. Most research has focussed on achieving this by alloying Pt with Fe, Co, Ni or Cu [1,2]. However, these compounds typically degrade under PEMFC conditions, due to dealloying. Alloys of Pt and rare earths may be inherently less prone to dealloying under reactions conditions, due to their negative enthalpy of formation.[2,3]

Herein, we present a systematic study on the trends in activity of nine novel Pt-lanthanide and Pt-alkaline earth electrodes ( $\text{Pt}_5\text{Ca}$ ,  $\text{Pt}_5\text{Sr}$ ,  $\text{Pt}_5\text{La}$ ,  $\text{Pt}_5\text{Ce}$ ,  $\text{Pt}_5\text{Sm}$ ,  $\text{Pt}_5\text{Gd}$ ,  $\text{Pt}_5\text{Tb}$ ,  $\text{Pt}_5\text{Dy}$  and  $\text{Pt}_5\text{Tm}$ ). These compounds are amongst the most active polycrystalline extended surfaces of Pt-based ever reported. Moreover, our recent study showed that  $\text{Pt}_x\text{Gd}$  is highly active in the nanoparticulate form.[4] On the bulk alloys, a Pt overlayer with a thickness of few Pt layers is formed under reaction conditions (Fig. 1A) [5]. It turns out that the lattice parameter is the descriptor for both the activity *and* stability of these materials (Fig 1B). We rationalise this finding using a density functional theory based model. We show that the lanthanide contraction can be used as tool to tune the catalyst performance.

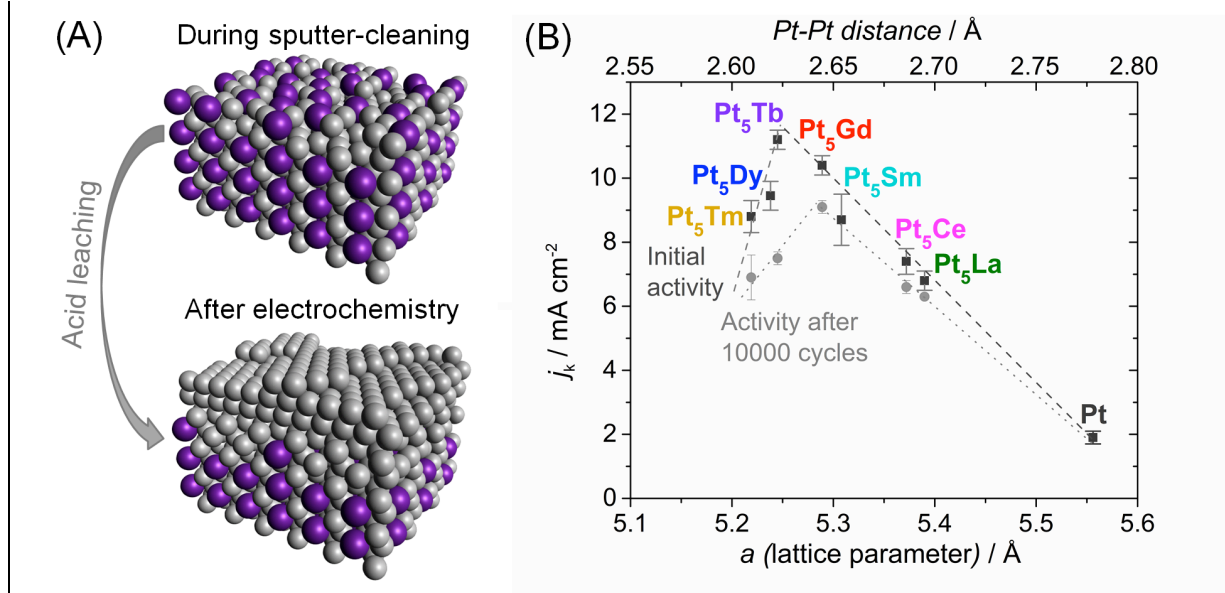

Fig 1. (A) Schematic three-dimensional views of the  $\text{Pt}_5\text{M}$  ( $\text{M}$  = lanthanide or alkaline earth metal) structure during sputter-cleaning and after electrochemistry. (B) Experimental 'activity-lattice parameter' volcano plot: ORR kinetic current density measured at 0.9 V vs. RHE as a function of the lattice parameter and the Pt-Pt distance for polycrystalline  $\text{Pt}_5\text{M}$  electrocatalysts after initial ORR activity (dark grey squares) and after 10 000 cycles between 0.6 and 1.0 V vs. RHE (grey circles).

Climate change is considered one of the greatest environmental threats of our times. The atmospheric concentration of greenhouse gases has increased steadily over the past century. Human activities produce an annual excess of 3.9% CO<sub>2</sub> to the natural carbon cycle. This raise in CO<sub>2</sub> emission has resulted in an increase of atmospheric CO<sub>2</sub> during the last 200 years from approximately 270 ppm to 385 ppm. This is thought to cause atmospheric warming, which is associated with a global climate change and a planetary temperature increase.

Strategies for reducing CO<sub>2</sub> buildup in the atmosphere includes: 1) reduction of the amount of CO<sub>2</sub> produced by increasing the energy efficiency or changing the primary energy source; 2) development of technologies for capture, sequestration and storage of CO<sub>2</sub>; and 3) use of CO<sub>2</sub> as raw material to generate high value-added chemical products. Moreover, the transformation of CO<sub>2</sub> into a value-added product represents a means to store energy in the form of chemical bond, allowing that energy to be readily transported and used elsewhere. This can be achieved by supplying physical energy in the form of electricity. Under that scheme, CO<sub>2</sub> conversion makes sense if the input energy is from a renewable source such as sunlight (photochemical process) or wind, solar and hydroelectricity (electrochemical process).

The ERC can proceed through two-, four-, six-, and eight-electron reduction pathways in gaseous, aqueous, and non-aqueous phases at both low and high temperatures. The major reduction products are carbon monoxide, formate/formic acid, oxalate/oxalic acid, formaldehyde, methanol, methane, ethylene, ethanol, amongst others. According to the reaction thermodynamics, the conversion of CO<sub>2</sub> into various organic compounds by electroreduction is not very demanding. However, challenges remain, such as the slow kinetics, even when electrocatalysts and high electrode reduction potential are applied.

Hori et al. conducted extensive studies on the electroreduction of CO<sub>2</sub>, emphasizing the important of defects (steps and vacancies) on the process [1]. More recently, Tang *et al* have discussed the importance of uncoordinated sites in the electrosynthesis of hydrocarbon [2]. Recent studies from Kanan's group have shown the high activity of oxide-derived copper foils for CO<sub>2</sub> and CO reduction [3,4].

In the present work, we have prepared a series of mesoporous Cu electrodes using the so-called dynamic hydrogen bubble tempting method. These electrodes were either used in their as-deposited state or oxidized in air and electrochemically reduced prior to being used for the electroreduction of CO. The electrodes thus formed were characterized by XRD, SEM and cyclic voltammetry. Following that, they were used as electrodes for the reduction of CO. In all cases, the products formed were H<sub>2</sub>, C<sub>2</sub>H<sub>4</sub>, C<sub>2</sub>H<sub>6</sub> acetate and ethanol. To the best of our knowledge, this is the first time ethanol production is reported from CO reduction on Cu. Under optimized conditions, the as-deposited mesoporous Cu electrode can achieve up to 42% current efficiency at potentials as low as -0.25 V RHE. In comparison, after oxide formation and reduction, the best mesoporous Cu electrode yields a current efficiency of only 35% at the same potential. However, the overall current on that last electrode is more than one order of magnitude higher than on as-deposited mesoporous Cu, which translates into a factor of two larger partial current for the production of value-added compounds.

## Introduction

There has been increasing interest in metal-air secondary batteries such as zinc-air secondary batteries. However, the large overpotential of air electrodes hinders the widely use of metal-air secondary batteries. In air electrodes, the electrochemical reactions occur only at the regions where three different species (electron, electrolyte, and oxygen gas) were transported, so-called triple-phase boundary (TPB) regions. Therefore, TPB regions in air electrodes have significant influences on the overpotential and the power density of metal-air batteries. Since practical porous gas diffusion electrodes are too complicated to be analyzed in detail, partially immersed electrode systems had been applied for the investigation of the properties of TPB regions as a model electrode. In our previous work using partially immersed electrode systems, it was found that thin liquid film effectively serves to expand TPB regions for ORR, but the liquid film hardly increases OER currents [1].

In practical air electrodes, influences of CO<sub>2</sub> should be considered. It was reported that some carbonate salts, such as K<sub>2</sub>CO<sub>3</sub>, precipitate in air electrodes and degrade their performance. In order to solve this problem, air electrodes using anion exchange membrane (AEM) were proposed [2]. In this case, TPB regions are formed on anion exchange ionomer. For the investigation of the property of the TPB regions formed on ionomers, partially immersed ionomer-coated electrode systems have been applied [3].

In this study, we investigate partially immersed anion exchange ionomer-coated Pt segmented electrodes as a model of the TPB region in AEM-typed air electrodes and compared with partially immersed Pt segmented electrodes, a model of the TPB region in conventional air electrodes. As an anion exchange ionomer, we use Tokuyama AS-4, which is one of the most widely used ones.

## Experimental

AS-4-coated Pt segmented electrodes (AS-4/Pt) were prepared by dropping of diluted AS-4 solutions on Pt segmented electrodes with a micro syringe. Schematic illustration of Pt segmented electrode was presented in elsewhere [1]. The thicknesses of AS-4 films were measured by a contact type surface roughness meter. A three-electrode electrochemical cell was used for electrochemical measurements. Partially immersed Pt segmented electrodes and partially immersed AS-4/Pt were used as working electrodes. A Hg/HgO electrode and Pt wire were used as a reference electrode and a counter electrode respectively. Aqueous solutions of KOH were used as electrolytes (saturated with mixed gases of O<sub>2</sub> and Ar at given ratio). Potentiostatic measurements were carried out under the mixed gases at the same ratios for KOH solution and steady-state oxygen reduction currents were measured. Segmental currents on Pt segments were also measured simultaneously with I-V converter.

## Result and discussion

Fig. 1 shows the segmental currents for cathodic oxygen reductions on partially immersed AS-4/Pt with 600 nm thickness of AS-4 film in an aqueous solution of 0.1 mol dm<sup>-3</sup> KOH (saturated with O<sub>2</sub>). Relatively high oxygen reduction currents were observed above 2.0 mm and the liquid levels on the electrodes were observed at 2.0 ~ 2.9 mm. Therefore, it was suggested that AS-4 film having contact with air served as an effective TPB region as with liquid thin films. However, total oxygen reduction currents were lower on AS-4/Pts than on Pt segmented electrodes. This is because oxygen transport properties and ion conductivities of AS-4 are still lower than those of KOH solutions.

# Catalytic Activities of Perovskite-type Oxide Thin Films and Single Crystals as Oxygen Electrodes in Alkaline Media

Yuto Miyahara, Kohei Miyazaki, Tomokazu Fukutsuka, and Takeshi Abe  
Graduate School of Engineering, Kyoto University  
Kyoto daigaku-katsura, Nishikyo-ku, Kyoto 615-8510, Japan  
myzkohei@elech.kuic.kyoto-u.ac.jp

There has been increasing interest in alkaline rechargeable zinc-air batteries because the battery offers a high theoretical energy density compared to current rechargeable batteries [1]. One of the advantageous features of this battery is that it has a wide range of selectivity for oxygen electrode catalysts because of the use of alkaline electrolytes. Since one of the biggest challenges of this battery is a high overpotential at an oxygen electrode, many researchers have tried to find oxygen electrode catalysts especially from cost-effective transition metal oxides. Most metal oxides have inadequate electronic conductivity as an electrode catalyst. Therefore, almost all the experiments in the literature employed so-called composite electrodes consisting of the oxides, conductive additives (such as carbon powders) and binders. This is also the case for perovskite type oxides, which are known as good oxygen electrode catalysts [2, 3]. In order to study the intrinsic electrochemical properties of the above oxides as an oxygen electrode, the use of model electrodes without any binders and conductive additives is desirable. In this research, therefore, electrochemical behaviors of perovskite oxides were evaluated using the thin films grown by pulsed laser deposition (PLD) method or the single crystals fabricated by floating zone (FZ) method.

Perovskite-oxide thin films were prepared by PLD method using Pt tip for a substrate [4]. As for the single crystals, FZ-grown perovskite rod was cut and polished to obtain desired lattice planes. Rotating disk electrodes (RDEs) were assembled using above thin films or single crystals and a RDE rod. For comparison, composite electrodes consisting of  $250 \mu\text{g cm}^{-2}$  perovskite particles,  $50 \mu\text{g cm}^{-2}$  Vulcan XC-72, and  $50 \mu\text{g cm}^{-2}$  anion conductive ionomer (AS-4, Tokuyama) were prepared on a glassy-carbon RDE. A three-electrode electrochemical cell was used as electrochemical measurements. RDEs, Pt wire, and reversible hydrogen electrode (RHE) were used as working, counter, and reference electrodes, respectively. For activity tests toward oxygen reduction reaction (ORR) and oxygen evolution reaction (OER), a solution of  $1.0 \text{ mol dm}^{-3}$  KOH (saturated by  $\text{O}_2$ ) was used as an electrolyte. For qualitative electronic conductivity measurements, a solution of  $1.0 \text{ mol dm}^{-3}$  KOH +  $20 \text{ mmol dm}^{-3}$   $\text{K}_3[\text{Fe}(\text{CN})_6]$  solution (saturated by Ar) was used as an electrolyte.

XRD measurement confirmed that phase-pure perovskite thin films were obtained by PLD. With respect to the result of electron conductivity measurements using ferricyanide/ferrocyanide, both perovskite thin films and perovskite single crystals showed good electronic conductivities. ORR polarization curves of  $\text{La}_{0.8}\text{Sr}_{0.2}\text{CoO}_3$  (LSCO) crystal and a composite electrode consisting of LSCO powder, Vulcan XC-72, and AS-4 were shown in Figure. This result suggested that ORR activity of LSCO crystal was quite low compared with that of composite electrode. Similar result was obtained when using perovskite thin films. As for OER, the activity difference between model electrodes and composite electrodes was smaller compared with the result of ORR. Detail will be discussed in the conference.

Figure. ORR polarization curves of pseudocubic  $\text{La}_{0.8}\text{Sr}_{0.2}\text{CoO}_3$ (110) crystal and composite electrode consisting of  $\text{La}_{0.8}\text{Sr}_{0.2}\text{CoO}_3$  powder, Vulcan XC-72, and AS-4.

# CO<sub>2</sub> Electroreduction on Heteroatom-doped Carbon Catalyst

Ana Sofia Varela, Wen Ju, Peter Strasser  
Technische Universität Berlin.  
Straße des 17. Juni 124 10623 Berlin, Germany  
ana.s.varelagasque@mailbox.tu-berlin.de

Direct electrocatalytic conversion of CO<sub>2</sub> to synthesis gas (H<sub>2</sub>/CO) and hydrocarbons is a promising alternative for the production carbon based chemicals. Ideally, the driving force for this process would be the surplus electricity from renewable sources allowing storing the excess of electricity as chemical energy [1].

Most of the studies on CO<sub>2</sub> electro-reduction (CO<sub>2</sub>RR) have focus on metallic catalyst, mostly Cu, which has a unique capability of producing considerable amounts of hydrocarbons. Nevertheless, on Cu the CO<sub>2</sub>RR poor selectivity and its place at high overpotentials, which implies important energy losses [2, 3]. Alternatively gold and silver have been studied for the reduction of CO<sub>2</sub> to form CO/H<sub>2</sub> mixtures which can be used in the production of synthetic fuels via the Fischer-Tropsch process [4]. To make this process technologically viable, however, it is crucial to find affordable and earth abundant catalyst.

For this contribution we will discuss our latest results on CO<sub>2</sub> electroreduction. In particular, we will focus on heteroatom-doped carbon catalyst. We show that these materials are highly active and selective towards the reduction of CO<sub>2</sub> to CO/H<sub>2</sub> mixtures outperforming gold catalysts. Furthermore we prove that sufficiently strong interaction between CO and the metal enables the protonation of CO and the formation of hydrocarbons. Our results highlight a promising new class of low-cost, abundant electrocatalysts for synthetic fuel production from CO<sub>2</sub>.

**Figure 1:** Faradaic selectivities of CO (a) and H<sub>2</sub> (b) and CH<sub>4</sub> (c) on gold (black), N-C (orange), Mn-N-C (red), Fe-N-C (green) and FeMn-N-C (blue); conditions: 10 minutes at constant electrode potential in CO<sub>2</sub> saturated 0.1M KHCO<sub>3</sub> at 0.785 mg/cm<sup>2</sup> catalyst loading. Lines to guide the eye.

# Activity and Selectivity of NiFe Layered Double Hydroxide Electrocatalyst for Seawater Electrolysis

Fabio Dionigi, Tobias Reier, Zarina Pawolek, Manuel Gliech and Peter Strasser  
*Technische Universität Berlin, Institut für Chemie,  
Straße des 17. Juni 124, 10623 Berlin, Germany.

Generation of hydrogen and oxygen from seawater electrolysis is an attractive process for fuel production since the majority of liquid water available to mankind at the Earth's surface is salty water.[1]

Chlorine evolution reaction (CER) is a competing reaction to oxygen evolution reaction (OER) when seawater is used as electrolyte. Although OER is thermodynamically favored over CER, the poor kinetics of the OER makes CER the dominant reaction in many catalytic systems.

NiFe layered double hydroxide (LDH) has been reported to catalyze the OER reaction in alkaline media at low overpotentials comparable with the performance of noble metals catalysts.[2] In our study, its activity and stability for seawater oxidation have been investigated with a rotating disk electrode in chloride containing electrolytes with basic and slightly basic pH. The electrochemical experiments are combined with products analysis (Figure 1) in order to estimate the selectivity for oxygen evolution. In particular, CER and hypochlorite formation are investigated by an in-line quadrupole mass spectrometer (QMS) and iodometric titration respectively.

NiFe LDH shows a high selectivity for OER in alkaline electrolytes (pH 13) containing 0.5 M NaCl, a chloride ions concentration typical of seawater. In 0.3 M borate buffer (pH 9.2) with 0.5 M NaCl the electrochemical experiments show degradation in performance at current densities approaching 10 mA/cm<sup>2</sup>, despite the high selectivity at lower current densities. This degradation of the anodic current is not observed in pH 13 (0.1 M KOH) in the presence of the same concentration of NaCl.

Despite the effect of the other ions present in seawater has not been tested yet, NiFe LDH shows promising results for its application as anode in a seawater electrolyzer operating under alkaline pH.

**Figure 1.** Oxygen evolution measured with a QMS during chronopotentiometry experiments at 1 mA, 5 mA, 10 mA and 20 mA for 15 min each. The blue lines are the expected O<sub>2</sub> level if selectivity were 100%. Catalyst: NiFe LDH on carbon Vulcan in 0.1 M KOH (pH 13) electrolytes containing 0.5 M NaCl.

## Abstract

Searching for inexpensive hydrogen evolution reaction (HER) electrocatalysts with high activity has attracted considerable research interest in the past years. Reported herein is the fabrication of self-supported Co<sub>4</sub>FeP nanosheets arrays on commercial carbon cloth (Co<sub>4</sub>FeP/CC) from its Co<sub>4</sub>FeLDH/CC precursor by a low-temperature phosphidation reaction. Remarkably, as an integrated three dimensional hydrogen-evolving electrocatalyst, Co<sub>4</sub>FeP/CC maintains its activity for at least 20 hours and exhibits a Tafel slope of 50.72 mVdec<sup>-1</sup> in acidic solution. Catalytic current density can approach 10 mAcm<sup>-2</sup> at an overpotential of 49 mV. Synergistic effect of Co and Fe has been shown to significantly improve the acid stability and show almost the same HER activity as noble metals such as Pt.

**Figure 1.** (A) Representative SEM images of Co<sub>4</sub>FeP on carbon cloth and (B) Polarization curves of Co<sub>4</sub>FeP/CC initially and after after 5000,8000cycles at a scan rate of 100 mV/s between 0 and -0.15 V vs RHE (0.5M H<sub>2</sub>SO<sub>4</sub>)

Actually platinum is still the most common metal catalyst in both anode and cathode fuel cell. In spite of the many attempts made in the last decade to develop non-Pt based catalysts for low temperature air cathodes, Pt remains the catalyst of choice, at least for acid based fuel cells. The situation in alkaline electrolytes is rather different; due to the stability of non-noble metals in this environment, many more opportunities are available for the development of non-Pt catalysts for the Oxygen Reduction Reaction (ORR) and for the Ethanol Oxidation Reaction (EOR). To completely remove Pt and to replace it with less expensive materials, bimetallic electrocatalysts have been proposed to exploit a synergic mechanism with one metal able to break the O-O bond of the molecular oxygen at the cathode side and the second metal effective in reducing the adsorbed oxygen so formed [1]. An alternative approach to the design of promising electrocatalysts for the fuel cell application is represented by light-heteroelement doped carbon nanomaterials (CNMs), and in particular nitrogen-doped CNMs (N-CNMs) [2]. In this contest we report the contribution of two different and parallel way to synthetize and test new electrocatalysts for the ORR:

- 1) Trying to combine by electrodeposition low-cost and Pt-free metal catalysts in order to match and directly act on the rate determinate step of the ORR.
- 2) Experimentally testing and designing of N-Decorated Nanomaterials in order to univocally identify the active site of reaction.

For point one, Silver and cobalt, whose catalytic activity against the ORR have been reported long ago [3-4] were combined together by electrodeposition on a glassy carbon electrode. The activity of the small amount of the binary Ag-Co catalyst ( $17 \mu\text{g cm}^{-2}$ ) were compared with the catalytic activity of the only-silver deposits that had given the best catalytic effect in Ref 5 and the rotating ring electrode (RDE) measurements were performed to estimate the average number of exchanged electron during the reaction. On the other hand a starting new method of surface modification of carbon nanotubes by N-Decoration via Aryldiazonium Salt (Tour) protocol [6] was used to study the contribution of pyridine groups on the ORR. Following our preliminary studies on acridine- and pyridine-functionalized carbon nanotubes the catalytic activities of new samples were estimated by rotating ring disk electrode (RRDE) measurements in order to clarify the main contribution of the substituted pyridine groups.

# Porphyrin-Polyoxometalates@Pt Modified Electrodes for Electrocatalytic Hydrogen Evolution Reaction

Dejin ZANG, A. Bonnefont, L. Ruhlmann\*

Laboratoire d'Electrochimie et de Chimie Physique du Corps Solide, Université de Strasbourg, 4 rue Blaise Pascal, 67000, Strasbourg, France

[dejin.zang@etu.unistra.fr](mailto:dejin.zang@etu.unistra.fr), [lruhlmann@unistra.fr](mailto:lruhlmann@unistra.fr)

Polyoxometalates (POMs) are anionic, nanometer-sized clusters of highly oxidized early transition metals and oxygen with a wide span of physical and chemical properties (redox, electronic, charge, bioactivity, etc.)<sup>[1]</sup>. They can also be used for the stabilisation of metallic nanoparticles due to their negative charge and their interaction with metals. In the recent years, the combination of POM with metallic nanoparticle catalysts was found to exhibit interesting activity and selectivity for some catalytic reactions in water and organic solvent.<sup>[2]</sup>

Various types of electrostatic porphyrin-POM@Pt films were synthesized and their activities of the electrocatalytic hydrogen evolution reaction were tested (cf. Figs. 1,2 and 3).

For instance, the multilayer films  $[\text{H}_2\text{PhMe}_3\text{P}^{4+} \cdot 4\text{TsO}^- / \text{Zn}_4(\text{H}_2\text{O})_2(\text{P}_2\text{W}_{15}\text{O}_{56})_2^{16-} 16\text{Na}^+ @\text{Pt}]_n$  were uniformly assembled in a sequential layer-by-layer way (LBL) onto ITO electrode (Fig. 2)<sup>[3]</sup> with varied numbers of cycle of deposition  $n$  ( $n = 0.5, 1, 2, 5, 10, 15, 20$ ). The first step is the formation of one monolayer of cationic porphyrin ( $n = 0.5$ ), then the modified electrode is dipped in the solution containing POM@Pt nanoparticles ( $n = 1$ ). The process is repeated several times in order to increase the thickness of the films and  $n$ . The growth of the hybrid inorganic/organic film could be followed by UV-visible spectroscopy and in-situ electrochemical quartz microbalance.

Fig 1. Molecular structures of porphyrin and POM.

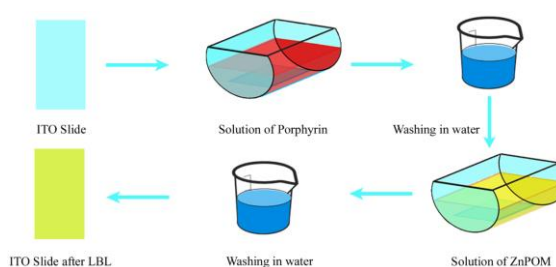

Fig 2. The procedure of layer by layer

Fig 3. Electrocatalytic hydrogen evolution reaction using  $[\text{TTMAP}/\text{Zn}_4\text{P}_4\text{W}_{30}@\text{Pt}]_n$  in aqueous solution,  $v = 10 \text{ mV s}^{-1}$ ,  $\text{pH}=6.5$ ,  $0.5 \text{ M H}_2\text{PO}_4^- / \text{HPO}_4^{2-}$  aqueous solution.

The multilayer films of  $[\text{TTMAP}/\text{Zn}_4\text{P}_4\text{W}_{30}@\text{Pt}]_n$  exhibit high catalytic activity for the hydrogen evolution reaction (Fig. 3).

## Abstract

In the recent years, the increasing of carbon dioxide in the atmosphere has been a problem in the world due to it might lead to global climate warming. Hence, using of CO<sub>2</sub> in synthesis of organic and inorganic compounds to decrease the CO<sub>2</sub> content of atmosphere has received considerable attention [1]. The large overpotential for reduction of CO<sub>2</sub> causes to low recycling efficiency of this molecule to useful products [2]. Hence, finding catalysts to decrease high overpotential and to increase the selectivity of the reduction processes has become an important concern.

In this work, N,N-bis(3-hydroxy-2-naphthaldehyde)-m-phenylenediamine (NMPD) was used as an excellent electrocatalyst for reduction of the carbon dioxide in an acetonitrile solution at room temperature. The CO<sub>2</sub> electrocatalytic reduction mechanism was investigated by cyclic voltammetry. Voltammetric results indicate that the produced CO<sub>2</sub><sup>•-</sup>, in the presence of NMPD, acts as an intermediate to reduce pyridine [3]. The coulometry results and FTIR, <sup>1</sup>H, <sup>13</sup>C NMR characterization proved the isonicotinic acid formation. In constant potential coulometry, constant potential of -2.0 V was applied to the working electrode. The results showed that the pyridine conversions were about 100% after passing 2.9 F mol<sup>-1</sup> of the starting compound (pyridine) at room temperature. The determined yield of isonicotinic acid was about 75%. Finally, it was suggested the electrocatalytic activated CO<sub>2</sub> has a dual activity toward pyridine and an ECC'C mechanism was proposed for isonicotinic acid production.

Perovskite Oxides ( $\text{ABO}_3$ ) with alkaline or rare-earth cations in the A-site and first row transition metal cations in the B-site have shown the potentials of being viable oxygen electrode catalysts in alkaline solution<sup>1</sup>. Furthermore, it was demonstrated that their physical-chemical properties as well as their catalytic activity can be significantly influenced by substitution or partial substitution of the A and/or B-site by other elements giving  $(\text{A}_x\text{A}'_{1-x})(\text{B}_y\text{B}'_{1-y})\text{O}_3$  compositions. A particular interesting case is the series of  $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$  oxides. It was reported that this series of oxides possessed interesting evolutions of physical-chemical properties as a function of Sr fraction, in terms of conductivity<sup>2</sup>, bulk structure<sup>3</sup> and amount of oxygen vacancies<sup>4</sup> in the lattice. Hence, in the present work, we report a thorough bulk structure, surface and electrochemical study of the series of  $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$  oxides ( $x=0, 0.2, 0.4, 0.6, 0.8, 1$ ) which allows us to draw important conclusions of the influence of bulk and surface properties of perovskite materials on the electrochemical activity towards the OER.

While some reports showed that the oxidation state of the Co cations in the  $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$  might be changed from  $3^+$  to  $4^+$  varying the Sr content in the oxide series<sup>3</sup>, other authors reported that no significant Co oxidation state change occurred with the Sr substitution<sup>5</sup>. To clarify the effect of Sr substitution on the Co oxidation state of  $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$  series, X-ray absorption measurements were carried on some of as prepared  $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$  oxides. Moreover, the surface segregation of Sr among the  $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$  oxides is well known<sup>6</sup>. This effect may block the active site at the oxide surface and, thus, need to be carefully investigated. Furthermore, discrepancy between theoretical and experimental studies could be easily understood only if the actual catalyst surface is accurately investigated. Herein, we also report the surface characterization by X-ray photoelectron spectroscopy (XPS). The bulk structure of the oxides was characterized by X-ray diffraction (XRD), combined with ex-situ conductivity, scanning electron microscope and specific surface area (BET) analyses. The oxygen evolution reaction (OER) was investigated by cyclic voltammetry and chronoamperometric measurements.

Our result shows that when the La is replaced by Sr gradually, a phase transition from Rhombohedral ( $\text{LaCoO}_3$ ) to cubic structure ( $\text{La}_{0.8}\text{Sr}_{0.2}\text{CoO}_3$ ) occurs combined with the aligning of Co-O-Co angle. The latter enhances the overlap between the occupied O-2p valence band and the unoccupied Co-3d conduction bands, which is considered as one of the main parameter that describes the increase of ex-situ electronic conductivity of  $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$  oxides as a function of Sr fraction. Moreover, the trend of the OER activity vs. conductivity suggests a correlation between the ex-situ electronic conductivity and the OER activity of  $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$  oxides. Therefore, we propose that OER activity of  $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$  oxides is related to the electronic structure of the oxides, that is, the OER activity could be improved by enhancing the overlap between the occupied O-2p valence band and the unoccupied Co-3d conduction bands.

# Electrocatalytic oxidation of urea on Ni(II)cyclam-modified nanoparticulate TiO<sub>2</sub> anodes for promoting the H<sub>2</sub> evolution on Pt counterelectrodes

J. Manríquez,<sup>1</sup> S. Murcio-Hernández,<sup>1</sup> J.J. Pérez-Bueno,<sup>1</sup> S. Sepúlveda<sup>2</sup>

<sup>1</sup> Centro de Investigación y Desarrollo Tecnológico en Electroquímica S.C., Parque Tecnológico Querétaro s/n, Sanfandila, 76703, Pedro Escobedo, Querétaro, México.

<sup>2</sup> Centro de Innovación, Investigación y Desarrollo en Ingeniería y Tecnología, Universidad Autónoma de Nuevo León, Nuevo León, México.

\*e-mail: [jmanriquez@cideteq.mx](mailto:jmanriquez@cideteq.mx)

In this investigation we studied the electrochemical oxidation of urea (Reaction 1, Scheme 1) on Ni(II)cyclam-modified nanoparticulate TiO<sub>2</sub> anodes (**OTE/npTiO<sub>2</sub>/Ni(II)cyclam**), where optically transparent electrodes (OTEs) were utilized as electrons collectors. Thereafter, this anodic reaction was coupled with polycrystalline Pt cathodes, where the H<sub>2</sub> evolution (Reaction 2, Scheme 1) was promoted in alkaline aqueous medium. For comparison purposes, the Reaction 2 was also promoted on Pt cathodes when Ni(II)cyclam-modified OTEs (**OTE/Ni(II)cyclam**) were utilized for carrying out the Reaction 1.

Scheme 1

Our results showed that the standard potential for the H<sub>2</sub> evolution ( $E^0_{\text{H}_2\text{O}|\text{H}_2} = -0.83\text{V vs. NHE}$ ) was measured on the Pt cathode when a potential of 1.0V vs. NHE was applied to the **OTE/npTiO<sub>2</sub>/Ni(II)cyclam**/electrolyte interface (where the urea oxidation was taking place) with the aid of a potentiostat. On the contrary, the standard potential for the H<sub>2</sub> evolution was achieved on the Pt electrode when a potential of 1.2V vs NHE was applied to the **OTE/Ni(II)cyclam**/electrolyte interface (in order to promote the urea oxidation). These interesting results demonstrated that the applied potential for promoting the urea oxidation on Ni(II)cyclam-modified electrodes was 0.2V-shifted in cathodic sense in the presence of nanoparticulate TiO<sub>2</sub> films, thus revealing a remarkable electrocatalytic phenomena which can be attributed to the surface composition of the TiO<sub>2</sub> nanoparticles.

## Introduction

Anode of alkaline water electrolysis (AWE) is usually Ni based material which is stable under steady electrolysis<sup>1)</sup>. However, durability of Ni based anode should be improved to connect with unstable renewable energies, because it deteriorates under potential cycling. In order to improve durability and activity against fluctuating electricity, the lithium doped NiO coated Ni anode ( $\text{Li}_x\text{Ni}_{2-x}\text{O}_2/\text{Ni}$ ) has been proposed<sup>2)</sup>. The  $\text{Li}_x\text{Ni}_{2-x}\text{O}_2/\text{Ni}$  had high stability and conductivity, but the relationship between the conductivity and lithium amount has been unclear. In this study, we have investigated the effect of increasing  $x$  of  $\text{Li}_x\text{Ni}_{2-x}\text{O}_2$  on the electronic conductivity and the catalytic activity for oxygen evolution reaction (OER) in alkaline medium.

## Experimental

A LiOH coated Ni plate (The Nilaco corp., 99.4%) was oxidized at 1000 °C for 1 h in air to prepare a  $\text{Li}_x\text{Ni}_{2-x}\text{O}_2/\text{Ni}$  working electrode. The  $x$  in  $\text{Li}_x\text{Ni}_{2-x}\text{O}_2$  was varied from 0 to 0.36. A Ni coil and reversible hydrogen electrode (RHE) were used as a counter electrode and reference electrode, respectively. All measurements were performed with three-electrodes electrochemical cell at  $30 \pm 1^\circ\text{C}$ . The electrolytes were 7.0 M (=mol dm<sup>-3</sup>) of KOH.

Resistance of the surface oxide layer was measured by electrochemical impedance spectroscopy with frequency range from 0.1 to 10<sup>5</sup> Hz. The catalytic activity for the OER was evaluated by slow scan voltammogram (SSV) between 0.7 and 1.8 V vs. RHE with scan rate of 5 mVs<sup>-1</sup>.

## Results and discussion

Surface resistances of  $\text{Li}_{0.10}\text{Ni}_{1.90}\text{O}_2$ ,  $\text{Li}_{0.14}\text{Ni}_{1.86}\text{O}_2$  and  $\text{Li}_{0.36}\text{Ni}_{1.64}\text{O}_2$  were 8.2, 7.5 and 4.9  $\Omega\text{cm}^2$ , respectively. It decreased with the increase of  $x$  in  $\text{Li}_x\text{Ni}_{2-x}\text{O}_2$  in all experimental conditions of this study.

Figure 1 shows polarization curves of the  $\text{Li}_x\text{Ni}_{2-x}\text{O}_2/\text{Ni}$  in 7 M KOH at 30°C. The  $\text{Li}_x\text{Ni}_{2-x}\text{O}_2/\text{Ni}$  whose  $x$  was from 0.10 to 0.29 had significantly higher catalytic activity than others for the OER. Their Tafel region of these electrodes, all slopes were showed around 50 mVdec<sup>-1</sup>, which was almost same as that of Ni. On the other hand, the catalytic activity for the OER on  $\text{Li}_x\text{Ni}_{2-x}\text{O}_2/\text{Ni}$  whose  $x$  was 0.36 was much lower than that whose  $x$  was below 0.29. Therefore, the conductivity of surface oxide was increased with  $x$ , but excess lithium doping decreased the activity for the OER.

Fig. 1 Polarization curves of the  $\text{Li}_x\text{Ni}_{2-x}\text{O}_2/\text{Ni}$  at  $30 \pm 1^\circ\text{C}$  in 7M KOH.

Nowadays the problem of water pollution has become more relevant for three main reasons: the first one is the increment in the generation of pollutants, the second one is that has increased awareness of the risk posed to the environment and the third one has arisen by the high cost of remediation. For the previous reason, remediation technologies that help to restore contaminated areas are very important.

Within remediation technologies highlights the electro-remediation due to many factors, such as its efficiency, its short operation time and a great ability to work with a wide range of contaminants. Currently there are factors that can be study and tested to improve this technology. A key factor is the coating of the electrodes employed for the treatment of contaminated waters, which plays a key role in the efficiency of the remediation process. The ability to modify electrodes provides a path of great importance to improve the performance thereof in the process of electro-remediation.

This research identifies the synthesis technique as painting and electrophoresis as the best for coating the electrodes with iridium oxide and tantalum oxide for the removal of hydrocarbons in contaminated water as Phenanthrene, Naphthalene and Fluoranthene with efficiencies major than 80 % in menus of 180 min. This degradation of hydrocarbons was by the presence of radical hydroxyls and active chlorine in interface produced during the electrokinetic treatment of polluted soil by hydrocarbons.

# A study of the Formation of $\text{Co}_{1-x}\text{Fe}_x\text{S}_2$ in Microwave Synthesis and its Electrocatalytic Properties towards Oxygen Reduction and Hydrogen Evolution

Gert Göransson, Alexander Björling and Elisabet Ahlberg  
Department of Chemistry and Molecular Biology, University of Gothenburg  
Box 100, 405 30 Gothenburg, Sweden  
gert.goransson@chem.gu.se

Pyrite ( $\text{FeS}_2$ ), the most abundant sulphur mineral in the Earth surface environment well known and studied since several centuries back, has received growing attention in the research community in the last years. All the transition metals from Mn to Zn can form disulphide pyrite type structures, all with different electronic and magnetic properties [1].  $\text{FeS}_2$  is classified as a van Vleck paramagnetic semiconductor and  $\text{CoS}_2$  as a ferromagnetic metal, a mixture of the two in complete solid solution is expected to be a compound with half-metal properties. The increased interest for tuning the band gap by doping e.g.  $\text{FeS}_2$  structure with other elements has its origin in the need of this kind of control in the construction of future spintronic and photovoltaic devices. Another field with great needs for compounds with tuneable conduction bands is electrocatalysis and in this work two of the most important reduction reactions in the aspect of green chemistry, oxygen reduction and hydrogen evolution, are studied.

$\text{Co}_{1-x}\text{Fe}_x\text{S}_2$  was chosen as a tuneable compound on the basis that Co is known to reduce  $\text{O}_2$  to either  $\text{H}_2\text{O}$  or  $\text{H}_2\text{O}_2$  depending on its environment, where a less electron “rich” environment gives mainly  $\text{H}_2\text{O}_2$  [2, 3]. Introduction of Fe into a  $\text{CoS}_2$  structure may slow the electron “availability” down and possibly favour reduction to  $\text{H}_2\text{O}_2$ , but still be conductive enough to provide fast total kinetics.

Various compositions of  $\text{Co}_{1-x}\text{Fe}_x\text{S}_2$  have been made using high temperature synthesis [4] or by hydrothermal synthesis [5], the latter method was chosen in this study and both conventional oven and microwaves (MW) were used and compared as heating sources. A simple aqueous solution with di-valent metal ions and thiosulphate as the sulphur source was used. However, the only phase pure compound that was readily formed without additives was  $\text{Co}_{2/3}\text{Fe}_{1/3}\text{S}_2$ . Certain mechanistic insights were given by comparing oven and MW synthesis, as the time frame of the heating ramp is different. XRD and SEM was used to characterise the products.

The  $\text{MS}_2$  materials were attached to a gold electrode by the ability of sulphur to form bonds with gold. The kinetics for oxygen reduction and hydrogen evolution will be presented.

Figure 1. MW synthesised  $\text{Co}_{2/3}\text{Fe}_{1/3}\text{S}_2$ .

Figure 2.  $\text{O}_2$  reduction on a rotating  $\text{Co}_{2/3}\text{Fe}_{1/3}\text{S}_2$  covered Au electrode.

# Preparation and Characterization of Platinum Nanoparticles Supported on Silica-Carbon Black Nanocomposites for Methanol Oxidation Reaction

Cheng-Lan Lin, Ju-Yu Yeh

Department of Chemical and Materials Engineering, Tamkang University  
No. 151, Yingzhuan Rd., Tamshui Dist., New Taipei City 25137, Taiwan  
cclin@mail.tku.edu.tw

Electrocatalysts composed of platinum nanoparticles supported on silica-carbon black nanocomposites (Pt/SiO<sub>2</sub>-C) for methanol oxidation reaction (MOR) are prepared and characterized in this study. Silica nanoparticles are firstly synthesized by sol-gel method on Vulcan XC-72 carbon black surface to form SiO<sub>2</sub>/C composites, and Pt nanoparticles are then decorated onto the composites using polyol method to obtain Pt-SiO<sub>2</sub>/C electrocatalysts. Electrocatalysts with SiO<sub>2</sub>/C weight ratio of 2/98 to 12/88 are prepared and the Pt loading of the electrocatalysts is measured using inductively coupled plasma-optical emission spectroscopy to be ~20 wt%. The average diameter of the Pt nanoparticles is about 3 nm as estimated from transmittance electron microscope images. Electrochemical properties and MOR performances of the electrocatalysts are investigated using cyclic voltammetry, chronoamperometry and CO-stripping voltammetry. The results indicated that Pt/SiO<sub>2</sub>-C electrocatalysts have superior MOR catalytic activity, more negative surface-absorbed CO oxidation onset potential, averagely larger electrochemical active surface area and better stability than a commercial E-TEK Pt/C electrocatalyst. Electrochemical impedance spectroscopy analysis showed that the Pt/SiO<sub>2</sub>-C electrocatalyst with the SiO<sub>2</sub>/C weight ratio of 8/92 has comparable charge transfer resistance as the commercial E-TEK PtRu/C electrocatalyst, and suggested that the bi-functional mechanism might be responsible for the enhanced MOR performance. It is envisioned that the Pt/SiO<sub>2</sub>-C might served as new potential candidate of the MOR electrocatalyst for direct methanol fuel cell.

Figure 1 TEM image of a Pt/SiO<sub>2</sub>-C electrocatalyst.

Figure 2 Cyclic voltammograms of the Pt/SiO<sub>2</sub>-C electrocatalysts in 0.5 M H<sub>2</sub>SO<sub>4</sub> solution containing 1.0 M methanol.

# Multi-Components Amorphous Metal-Oxides Catalysts for Oxygen Evolution Reaction

Chia-Ying Chiang, Po-Tso Ting

*Department of Chemical Engineering, National Taiwan University of Science and Technology  
Taipei, Taiwan (106)  
cychiang@mail.ntust.edu.tw*

With the rapid development of economy and industry, global energy demand increases enormously. People use petroleum as energy source for a long time, while the stock of this finite source decreases rapidly. Moreover, in order to protect environment, clean and renewable energy sources are considered to replace petroleum, which is a finite source and causes air pollution. Hydrogen energy source producing from water splitting is one of the best ways to solve energy source insufficient, protecting environment. Recently, photovoltaic system combines with dc-dc converter and electrolyzer is a common way to produce hydrogen and oxygen by water electrolysis. However, the conversion efficiency of this system is only 8%, and the potential of producing hydrogen is around 1.9 V, which is largely higher than the minimum potential of hydrogen production by water splitting (1.23 V). The main restriction of photovoltaic system is on the performance of electrodes. Efficiency of producing hydrogen and oxygen depends on the catalytic efficiency of electrode. Furthermore, the reaction of water splitting is primary controlled by the extremely low rate of oxygen production process. Until now, the most efficient catalysts of producing oxygen in water splitting are noble metal, which is rare and the cost is high. These two characteristics of noble metal are not suitable for mass production. Therefore, the object of this research is to find a material which is cheap, abundant on earth's upper crust, stable over a long period of time, and has high current density ( $>0.5 \text{ mA/cm}^2$ ) at low overpotential ( $< 0.3 \text{ V}$ ).

Metal oxides are considered as the stable catalysts which have high catalytic activity for oxygen evolution reaction (OER), such as  $\text{IrO}_2$ , spinel solids and amorphous metal oxides. In addition, amorphous metal oxides have been proved that they have potential to replace noble metal as OER materials. Niobium is abundant on earth's upper crust, and its oxide has been proved to have photochemical ability to produce oxygen in water splitting. Therefore, this research will focus on the series of niobium oxides for OER. Photochemical metal-organic deposition (PMOD) is one of the best ways to make amorphous thin films, due to the cost of this process is cheap, operating temperature and pressure are low, equipment is simple and it is suitable for multicomponent amorphous oxides preparation. In order to check the kinetic performance of catalysts, cyclic voltammetry curve (CV) is plotted. From the CV curve, cobalt oxide is a relatively high catalytic activity catalyst for OER, when the current density reaches  $0.5 \text{ mA/cm}^2$  while the potential only required 1.45 V. In addition, Iron oxide and niobium oxide require potential 1.63 V and 2.5 V, respectively, to reach the same current density. However, when cobalt doped with niobium and iron by the ratio of 1 : 2 : 2, the Tafel slope of  $\text{Nb}_{20}\text{Co}_{40}\text{Fe}_{40}$  is smaller than cobalt oxide. This indicates a more efficient catalyst is prepared. More detailed analysis and mechanism will be given in this talk.

# Development and Characterization of Nanostructured Multifunctional Materials for Photoelectrochemical and Electrocatalytic Reduction of Carbon Dioxide and Water Splitting

Pawel J. Kulesza

*Faculty of Chemistry, University of Warsaw, Pasteura 1, PL-02-093 Warsaw, Poland.  
pkulesza@chem.uw.edu.pl*

Through intentional and controlled combination of metal oxide semiconductors, we have been able to drive effectively photoelectrochemical reduction of carbon dioxide. The combination of titanium (IV) oxide ( $\text{TiO}_2$ ) and copper (I) oxide ( $\text{Cu}_2\text{O}$ ) has been explored toward the reduction of carbon (IV) oxide ( $\text{CO}_2$ ) before and after sunlight illumination. Application of the hybrid system composed of both above-mentioned oxides resulted in high current densities originating from photoelectrochemical reduction of carbon dioxide mostly to methanol ( $\text{CH}_3\text{OH}$ ) as demonstrated upon identification of final products. The role of  $\text{TiO}_2$  is not only stabilizing: the oxide is also expected to prevent the recombination of charge carriers.

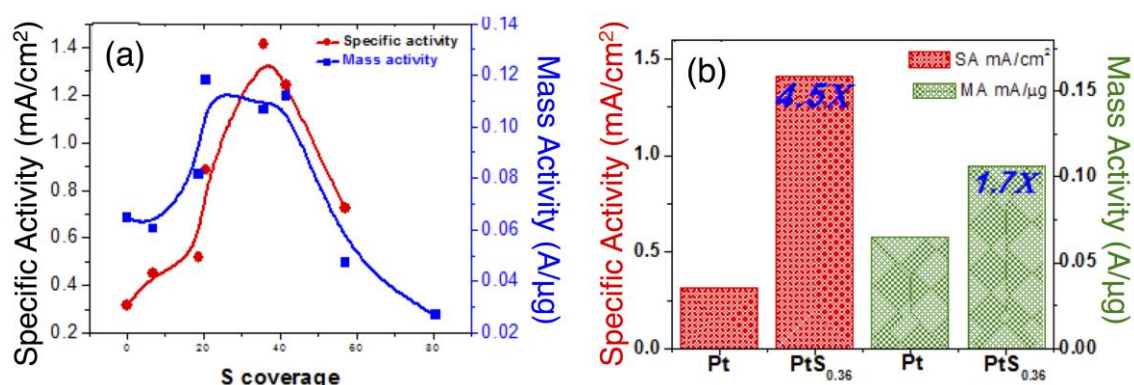

When it comes to the development of electrocatalytic systems for reduction of carbon dioxide, instead of conventional Pd (or Pt) nanoparticles, nanosized Pd (or Pt) immobilized within tridentate Schiff-base ligands of the supramolecular complex of the type,  $[\text{Pd}(\text{C}_{14}\text{H}_{12}\text{N}_2\text{O}_3)\text{Cl}_2]_2 \cdot \text{MeOH}$ , have been considered. Reduction of carbon dioxide begins now at less negative potentials and is accompanied by significant enhancement of the  $\text{CO}_2$ -reduction current densities. Among important issues are specific interactions between nitrogen coordinating centers and metallic palladium sites at the electrocatalytic interface.

There has been growing interest in the development of photoanode materials for sunlight-driven oxygen generation (photoelectrochemical water splitting to oxygen and hydrogen). Among important issues is that the semiconducting oxide should be characterized by indirect optical transition in the visible part of the solar spectrum. We demonstrate here utility of gold and hematite nanoparticles (modified or stabilized with simple and derivatized Keggin-type molybdate and tungstate polyoxometallates) to enhance photocurrents generated by mesoporous tungsten trioxide,  $\text{WO}_3$ , photoanodes irradiated with visible light in aqueous solutions. The possibility of the plasmonic effect and interactions between the gold plasmons will be addressed. Independent diagnostic experiments, voltammetric with Pt microdisk electrode and amperometric type with Clark oxygen sensor, have confirmed the appearance of oxygen during photooxidation of water. In a case of the enhancement effect at  $\text{WO}_3$  films doped with borotungstic acid-stabilized hematite, the observed phenomena could be rationalized either in terms of the presence of new conduction band structures in doped  $\text{WO}_3$  films or a marked increase in the degree of hydration of the doped oxide structures.

# Unexpected Good Deed of a Traditional Poison: Sulfur-Adsorption Enhanced Activity and Stability of Pt for Oxygen Reduction Reaction

Yanyan Wang, YuYe J. Tong  
 Department of Chemistry, Georgetown University  
 37<sup>th</sup> and O Streets NW, Washington DC 20057  
 yyt@georgetown.edu

Sulfur is a well-known poison in both heterogeneous catalysis and electrocatalysis<sup>[1]</sup>. But recently, we have observed that it can also do good deeds: enhancing oxygen reaction (ORR)<sup>[2]</sup>, CO<sup>[3]</sup> as well as methanol oxidation reaction<sup>[4]</sup> on Pt. The adsorbed sulfur coverage dependence of ORR on commercial Pt black (Johnson-Matthey) obtained in a more detailed recent study is shown in Figure 1, confirming the previously observed activity enhancement effect. Moreover, we have observed recently that sulfur adsorption can also enhanced the stability of Pt black when the latter was subjected to accelerated stability test: after 40k potential cycles between 0.6V to 1.1V (vs. RHE) under saturated O<sub>2</sub> at room temperature, the electrochemical surface area (ECSA) of the S-adsorbed (~16%) Pt black was reduced by ~25% as compared to ~52% for pure Pt black, well above the DOE's 2017 target.

**Figure 1.** (a) The S-coverage dependent specific activity (left) and mass activity (right) of ORR on Pt black. (b) Comparison of the activities for the sample with 36% S-coverage with pure Pt black. 4.5 times and 1.7 times enhancement in specific activity and mass activity respectively were observed.

In this presentation, in addition to electrochemical data, we will discuss mechanistic insights afforded by in situ surface enhanced IR absorption and Raman spectroscopic studies on why sulfur adsorption can enhance ORR and stability of Pt black. The spectroscopic results obtained strongly suggest that S-adsorption induced enhanced O<sub>2</sub> adsorption and delayed Pt oxidation may well be the reasons for observed enhanced activity and stability.

# Synthesis of CoFe<sub>2</sub>O<sub>4</sub>/Nitrogen-doped Graphene and Its Catalytic Performance for ORR

Qingli Hao, Wu Lei, Lei Lu, Xifeng Xia

*Key Laboratory for Soft Chemistry and Functional Materials, School of Chemical Engineering, Nanjing University of Science and Technology  
Nanjing 210094, China*

*E-mail: qinglihao@njust.edu.cn; haoqingli@yahoo.com*

Due to the sluggish kinetics of oxygen reduction reaction (ORR), the development of efficient electrocatalysts for ORR becomes the key task and main challenge in the renewable energy technologies. Platinum (Pt) and Pt-based alloys are the best known and most active ORR catalysts, but the high cost, their low durability and poor susceptibility to poisoning definitely limit the commercialization of Pt-based catalysts<sup>[1-4]</sup>. Herein, we report a nanostructured hybrid CoFe<sub>2</sub>O<sub>4</sub> loaded on N-doped reduced graphene oxide (CoFe<sub>2</sub>O<sub>4</sub>/NG) as an efficient synergistic ORR catalyst. The hybrid was prepared through a facile one-step solvothermal method followed by calcination. It exhibited a comparable catalytic activity as commercial Pt/C with a preferential four-electron pathway in the ORR, while it outperformed Pt/C in terms of stability and resistance to CO poisoning and methanol crossover. It was able to fully combine the advantages of both CoFe<sub>2</sub>O<sub>4</sub> nanoparticles and N-doped reduced graphene oxide, achieving a more positive ORR onset potential than CoFe<sub>2</sub>O<sub>4</sub> loading on non-doped reduced graphene oxide in the previous literature. Moreover, the multi-metal oxide shows better catalytic activity to ORR than the single metal oxide does. Interestingly, we found high crystalline degree of spinel CoFe<sub>2</sub>O<sub>4</sub> can contribute to its excellent onset potential in ORR activity of CoFe<sub>2</sub>O<sub>4</sub>/NG, apart from the active nature of CoFe<sub>2</sub>O<sub>4</sub>/NG. Therefore, its simple preparation method, low-cost, efficient catalytic activity, excellent stability and great resistance to CO poisoning and methanol crossover can make CoFe<sub>2</sub>O<sub>4</sub>/NG a promising ORR catalyst to replace the high costly commercial Pt/C.

## Electrocatalytic Materials

In order to solve the global warming and carbon dioxide emission problems caused by the fossil fuels, new technologies for solar energy conversion and storage into chemical energy, hydrogen, are now attracting attention. Now a day's hydrogen is generally produced from fossil fuels and from water electrolysis by using electricity. Hydrogen could take its merit position in the global energy sector, if hydrogen could be efficiently produced with low cost and simple ways by using alternative energy resources. Sustainable, renewable, and clean hydrogen can be produced if solar energy is used as energy source and water is used as hydrogen source in hydrogen production system. In these type systems, solar energy converted into electricity with proper methods is used indirectly in water electrolysis or directly used to convert water to chemical energy as hydrogen energy [1,2]. Presently, the solar-to-hydrogen energy conversion efficiency is too low for the technology to be economically sound. Consequently, a high-performance system therefore needs to be developed for a sustainable hydrogen energy system. In the scope of this study, to produce efficient and low cost hydrogen by using alternative energies with simple ways; **we designed and optimized a “photocatalytic-electrocatalytic dual hydrogen production system (FEHUS)” which combined discontinuous photocatalytic and electrocatalytic systems in one continuous dual system.**

In the electrolysis chamber of FEHUS, which was design in study, an “electrocatalytic electrolysis system” (use solar energy indirectly) and in the photocatalytic chamber, a “photocatalytic hydrogen production system” (use solar energy directly) was used. In the photocatalytic chamber of FEHUS, photocatalysts, which are active in both of the UV and visible part of the light spectrum. As a result of the light absorption of photocatalysts, while water-hydrogen reduction reaction took place at the conduction band (CB) of the photocatalysts, sacrificial  $S^{2-}$  electrolyte oxidized to  $S_2O_3^{2-}$  with the help of  $SO_3^{2-}$  at the valance band (VB) of the photocatalysts.  $S_2O_3^{2-}$  produced in the photocatalytic chamber of FEHUS was used as redox species in the electrolysis chamber. Usage of  $S_2O_3^{2-}$  in the electrolysis chamber, the cell potential of water electrolysis considerably decreased. Moreover usage of electrocatalysts on the cathode decreased the over-potential of the cathode for the hydrogen reduction reaction.

$CuInS_2$ ,  $AgInS_2$ ,  $ZnS$ ,  $CdS$  and mixture of these ( $Cd_{(1-x)}Zn_xS$ ) and  $ZnS$ ,  $CdS$  and ( $Cd_{(1-x)}Zn_xS$ ) doped with  $TiO_2$  and  $WO_3$  were used as photocatalysts in the photocatalytic chamber of FEHUS. Phthalocyanines, azido functionalized graphene oxide ( $GO-N_3$ ) and azido functionalized reduced graphene oxides ( $RGO-N_3$ ), phthalocyanines decorated and azido functionalized reduced graphene oxides ( $RGO-N_3-MPCs$ ), and cobaloximes were used as electrocatalyst on the cathode of the electrolysis system of FEHUS. Overpotential of hydrogen evolution reaction on GCE decreased 0.50 V with electrocatalysts on the

cathode. Moreover water electrolysis potential decreased about 0.80 V, when electrolyte of photocatalytic reaction was used as the electrolyte of the electrolysis cell. Consequently, more efficient, cheap, simple, pure and oxygen-free hydrogen was produced with this newly developed FEHUS. With this study, solar energy was successfully stored as hydrogen with a more efficient manner in a FEHUS.

Polymer electrolyte fuel cells (PEFCs) play a key role in the development of sustainable automotive technology due to their low operating temperature, high energy densities and emission-free operation mode. Nevertheless, the large-scale production of these environmentally friendly devices is still constrained by the large overpotential arising from the oxygen reduction reaction (ORR) at the cathode, limiting their overall performance. Since state-of-the-art PEFC electrocatalysts all contain Pt, many efforts are being devoted to improve its electrocatalytic activity[1].

Varying the inter-atomic distance of Pt atoms to modify the adsorption properties of oxygen species on its surface represents a promising strategy [2]. In this context, we present a novel approach for producing a model Pt electrocatalyst with different inter-atomic spacing. Pulsed laser deposition was applied to prepare ultra-thin and differently strained Pt films on single crystalline strontium titanate substrates with (100) and (111) orientation. X-ray diffraction measurements confirmed their epitaxial orientation and high crystalline quality. *In situ* reflection high energy electron diffraction (RHEED) measurements revealed that the Pt films grow preferentially in a three dimensional Volmer-Weber mode. A distinct thickness-dependent morphology is observed by scanning electron microscopy..

The electrochemical surface properties of the as-produced Pt films were examined by cyclic voltammetry and CO stripping. The influence of varying inter-atomic Pt distances on the ORR activity was determined using a specifically designed flow cell.

Here we present the first results on the structural and the electrochemical analyses of the Pt films. It will be demonstrated that strained Pt films exhibit a superior activity towards ORR as compared to the single crystalline fully relaxed bulk structure.

# Determination of Oxygen Binding Energy from Simple Amperometric Experiments and its Application Towards the Evaluation of Novel Materials for the Oxygen Reduction Reaction

Samuel C. Perry, Guy Denuault  
University of Southampton  
University Road, Southampton SO17 1BJ, UK  
scp2g08@soton.ac.uk

Electrocatalytic activity of pure metals towards the oxygen reduction reaction (ORR) has been shown to be dependent on the binding energy of oxygen towards said metal ( $\Delta E_O$ )<sup>1</sup>, with platinum being regarded as the optimum noble metal for the ORR. Previously, the assessment of  $\Delta E_O$  for novel materials, metals and alloys required independent DFT studies for comparison with pure metal values in the literature. We present experimental results which offer an alternative means to evaluate the magnitude of  $\Delta E_O$  for ready comparison of materials using chronoamperometry at microdisc electrodes in aqueous media. When investigating the ORR on the millisecond timescale we found an unexpected additional chronoamperometric response for sampling times of less than around 50 ms, indicating that the ORR rate is not solely controlled by the diffusion of dissolved oxygen towards the microelectrode<sup>2,3</sup>. Careful analysis of this extra current under varying conditions with strict controls on electrode and solution conditions showed the extra current to be due to the reduction of pre-adsorbed dioxygen from the solution. When plotted against the binding energies reported to dioxygen, the associated charge ( $Q$ ) produces a calibration curve, Figure 1.

Figure 1: Extra charge calculated from the difference between experimental and theoretical current transients for the oxygen reduction reaction against the binding energy ( $\Delta E_O$ ) reported by Norskov et al.<sup>3</sup> for those metals toward oxygen. The connected sigmoid is intended as a guide for use as a calibration curve for the calculation of  $\Delta E_O$  from chronoamperometric data.

The constructed curve offers a simple means for the determination of  $\Delta E_O$  without the need for complex DFT or other computational analysis, thereby offering a method for a rapid interrogation of the ORR behaviour of a novel material. This is illustrated in Figure 1 with the determination of  $\Delta E_O$  for a mixed metal alloy from experimental data.

# Electrochemical CO<sub>2</sub> Reduction on Pd-based Bimetallic Catalysts

Ruud Kortlever<sup>1</sup>, Ines Peters<sup>1</sup>, Collin Balemans<sup>1</sup>, Meital Shviro<sup>2</sup>,

Youngkook Kwon<sup>1</sup>, David Zitoun<sup>2</sup>, Marc T.M. Koper<sup>1</sup>

<sup>1</sup>Catalysis and Surface Science, Leiden Institute of Chemistry, Leiden University

<sup>2</sup>Nanomaterials on Surfaces Lab, Bar-Ilan University

e-mail address: ruud.kortlever@gmail.com

The electrocatalytic reduction of carbon dioxide has attracted the interest of electrochemists and inorganic chemists for decades as a key reaction in facilitating a sustainable low-temperature redox cycle for energy storage and conversion.<sup>1</sup> However, major issues still need to be resolved before the reduction of CO<sub>2</sub> to fuels becomes practically feasible.<sup>2</sup> The main problems holding back electrocatalytic CO<sub>2</sub> reduction are the high overpotentials needed and the poor product selectivity and faradaic efficiency, since the hydrogen evolution reaction (HER) is a competing reaction in the potential window in which CO<sub>2</sub> reduction takes place. To overcome these problems new catalyst systems need to be developed that increase the product selectivity and efficiency of electrocatalytic CO<sub>2</sub> reduction, while simultaneously lowering the overpotentials.

In biological systems, formate dehydrogenase enzymes show efficient reduction of CO<sub>2</sub> to formic acid at low overpotentials. Armstrong and Hirst have recently discussed how these redox enzymes can reversibly catalyze reaction 1:<sup>3</sup>

but there is no fundamental reason why inorganic metallic catalysts could not do the same, since “reversible electrocatalysts” are expected to exist for two-electron transfer reactions.<sup>4</sup> Metallic catalysts that are very active for formic acid oxidation are mostly palladium- or platinum-based catalysts.

We have combined palladium and platinum; both by depositing (mono-)layers of palladium on a platinum substrate<sup>5</sup> and by synthesizing Pd<sub>x</sub>Pt<sub>(100-x)</sub>/C alloy nanoparticles and tested these materials for the reduction of CO<sub>2</sub>. These catalysts show a very low onset potential of 0.0 V vs. RHE for the reduction of CO<sub>2</sub> to formic acid in a pH 6.7 electrolyte. While the deposited layers of palladium on platinum show a very fast deactivation due to CO poisoning, the Pd<sub>x</sub>Pt<sub>(100-x)</sub> nanoparticles can be optimized to avoid such a fast deactivation and show a maximum faradaic efficiency of ~88% after 1 hour of electrolysis at -0.4 V vs. RHE for Pd<sub>70</sub>Pt<sub>30</sub>/C. Furthermore, since the Pd-Pt catalysts are also active for the oxidation of formic acid, we demonstrated that these catalysts can reversibly reduce CO<sub>2</sub> to formic acid and oxidize formic acid to CO<sub>2</sub> (See Fig. 1).

When Pd (mono)layers were deposited on an Au substrate the reduction of CO<sub>2</sub> yielded C<sub>1</sub> to C<sub>4</sub> hydrocarbons. The same products were observed for the reduction of CO<sub>2</sub> on PdNi alloy nanoparticles. This is an unique result, since until now only copper is known to produce C<sub>1</sub> and C<sub>2</sub> hydrocarbons. The formation of hydrocarbon products was studied by varying the Pd-layer thickness on bulk Au and on Au nanoparticles and as a function of PdNi alloy nanoparticles composition.

# ORR activities of Au-Modified Stepped Pt Single Crystal Electrodes

Kensaku Kodama, Ryosuke Jinnouchi, Naoko Takahashi, Hajime Murata, Yu Morimoto  
 Toyota Central R&D Labs., Inc.  
 41-1 Yokomichi, Nagakute, Aichi 480-1192, Japan  
 kkodama@mosk.tytlabs.co.jp

Pt nanoparticles are one of the most promising electrocatalysts for polymer electrolyte fuel cells (PEFCs), because of moderate oxophilicity of Pt metal surface for oxygen reduction reaction (ORR) and high specific surface areas with their morphologies. The activity and durability of Pt nanoparticles, however, still need to be improved for automobile applications. Among the various crystallographic sites on the particle, low-coordinated Pt atoms at the edge parts have been shown to have negligible contributions for the ORR activity and become the starting site of consecutive dissolutions of Pt because of their high oxophilicities [1, 2]. These observations suggest that replacing Pt atoms in the edge parts of a Pt nanoparticle by nobler Au atoms can improve the durability without reducing the ORR activity. Recently, Jinnouchi et al., using a first principles theory, showed that the Pt-Au replacements at the edge parts even improve the ORR activity by changing the oxophilicity of the Pt nanoparticle [2]. This prediction is experimentally tested using a model Pt surface in the present study.

Figure 1 shows the CVs for Pt (111), Pt (322), the structure of which is shown in Fig.2a, and the Au-modified Pt (322) (denoted Au/Pt (322)). By the Au-modification, the Pt (100)-step peaks at 0.29 V disappeared while the Pt (111)-terrace contribution between 0.05 – 0.4 V remained unaffected. This data suggests that the step Pt atoms have been selectively masked by Au atoms. (The selective masking was also supported by X-ray photoelectron spectroscopy; the number density of Au atoms on the Pt surface was consistent with that of (100) step sites.) Fig. 2b shows a possible structure, where the Au atoms occupy 4-fold hollow sites on the (100) step. The Au-modified structure, where the additional Au atoms form new steps and the original step Pt rows are regarded as the second rows from the edges of the new terraces, is an ideal model catalyst where the low-coordinated Pt atoms have been replaced by Au atoms.

Figure 3 shows the ORR polarization curves and Tafel plots of the ORR kinetic currents for Pt (111), Pt (322) and Au/Pt (322). The ORR-improving factors at 0.9 V are 2.8 from Pt (111) to Pt (322), and 1.4 from Pt (322) to Au/Pt (322), showing the definite improving effect of the Au modification, which agrees with the theoretical prediction [2]. The origin of the Au-effect as well as the step-induced ORR improvement will be discussed in the meeting.

In the present study the activity of the Co with a fiber structure decorated by Pt nanoparticles (denoted as Pt/Co<sub>fiber</sub>) was investigated towards the oxidation of hydrazine. The platinum-cobalt catalysts were deposited on the Cu surface using simple and cost-effective electrochemical and chemical methods. At first, Co coating with a fiber structure and the thickness of ~3 μm was electroplated onto the Cu surface. Then, the Pt nanoparticles were deposited on the prepared Co<sub>fiber</sub>/Cu by its immersion into the 1 mM H<sub>2</sub>PtCl<sub>6</sub> + 0.1 M HCl solution at the temperature of 25 °C for 10, 20 and 60 s, respectively. The morphology, structure and composition of the prepared catalysts were characterized by means of Field Emission Scanning Electron Microscopy, Energy Dispersive X-ray Spectroscopy and Inductively Coupled Plasma Optical Emission Spectroscopy. The electrocatalytic properties of catalysts were evaluated with respect to the oxidation of hydrazine in an alkaline medium by means of cyclic voltammetry and chrono-techniques.

It was found that the Pt loadings were 5.4, 15.4 and 28.7 μg cm<sup>-2</sup> in the prepared Pt(Co<sub>fiber</sub>)/Cu catalysts after the immersion of Co<sub>fiber</sub>/Cu into the platinum-containing solution for 10, 30 and 60 s, respectively. It was found that the cobalt with a fiber structure decorated with the platinum nanoparticles show enhanced electrocatalytic activity towards the oxidation of hydrazine in an alkaline medium as compared to that of bare Pt and Co deposited on the Cu surface.

# Pt (Pd) Monolayer on Au Formed by One-Pot Chemical Process with Enhanced Electrocatalytic Performance on Ethanol Oxidation

Han Wang, Wen-Bin Cai\*

*Collaborative Innovation Center of Chemistry for Energy Materials and Department of Chemistry, Fudan University, Shanghai 200433, China*  
wbcai@fudan.edu.cn

Low-abundance precious metals Pt and Pd are generally required in the anode catalysts of fuel cells to drive the electrocatalytic oxidations of small alcohol molecules. In order to maximize their utilization in practical catalysts, an effective way is to synthesize by design the Pt (Pd) monolayer (ML) shell-suitable core nanostructures in which the shell atoms can be fully utilized and the catalytic activity of Pt (Pd) shell may be enhanced by its interaction with the core. Besides other applications, Au@Pt and Au@Pd core-shell structured catalysts were reportedly favorable for the electro-oxidations of alcohol and formic acid, respectively<sup>[1]</sup>. So far, the widely recognized synthesis of Au@Pt(Pd)-ML is based on a two-step process involving an initial UPD of Cu on Au followed by galvanic redox replacement of Cu with Pt(Pd). That process requires external potential control, which is unfavorable for a scale-up fabrication<sup>[2,3]</sup>. Herein, with the delicate control over the concentration of Pt or Pd-precursor in a CO-containing solution, a ML of Pt, Pd or Pd+Pt can be deposited either on Au/C or on Au nanofilm at room temperature in one-pot chemical synthesis without any external potential control<sup>[4]</sup>. The ML formation was characterized on Au@Pt-ML/C with XRD and TEM-EDS measurement (Fig.1A) or on Au/Pt-ML film with ATR-IR measurement using CO as the surface probe. The as-synthesized Au@Pt-ML/C showed a remarkable enhancement in ethanol oxidation in terms of activity and durability (Fig.1B). The Au@M-ML/C also showed a pH sensitive activity toward ethanol electro-oxidation.

**Fig. 1** (A). XRD patterns of Au@Pt-ML/C, Au/C and Pt/C; (B). Chronoamperometric plots recorded at 0.75 V (RHE) in 1 M NaOH + 1 M ethanol.

# Bridging across Electrocatalytic Performances of Nanomaterials & Interfacial Species Evolution with Realtime ATR-IR Spectroscopy

Wen-Bin Cai\*, Kun Jiang, Ye Wang

Collaborative Innovation Center of Chemistry for Energy Materials and Department of Chemistry, Fudan University, Shanghai 200433, China  
wbcai@fudan.edu.cn

Over the past four decades, infrared spectroscopy with either external or internal reflection mode has played an important part in probing the electrode/electrolyte interface because of its capability to detect submonolayer change. With increasing application of electrocatalytic nanomaterials such as carbon supported or unsupported nanoparticles as well as nanofilms to hydrogen energy utilization including low-temperature hydrogen production and fuel cells<sup>[1,2]</sup>, a great deal of work has been aimed at the synthesis, characterization and performance of various electrocatalysts. In contrast, fewer investigations have been directed to the understanding of the electrocatalytic performances in terms of the corresponding interfacial chemistry at molecular level. To address the issue, we recently applied real time ATR-IR spectroscopy to investigate the interfacial molecular evolution during room-temperature hydrogen production from formic acid decomposition at Pd/C and Pd-B/C at OCP<sup>[1,2]</sup> as well as the electro-oxidation of formic acid on Pd black at constant and scanned potentials<sup>[2]</sup>. Also, *in situ* ATR-IR was extended for the first time to investigate the dealloying effect on ethanol oxidation reaction (EOR) at Pd-Ni-P nanofilm electrode in alkaline media<sup>[3,4]</sup>.

We monitored spectroscopically the accumulation of CO poisoning species and the simultaneous production of CO<sub>2</sub> at the solution side of the interface<sup>[1,2]</sup>. It is revealed that anti-CO poisoning nature of boron-doped Pd nanocatalyst at least partly contributes to its much higher turnover frequency (TOF) rate in hydrogen production. The CO accumulation at OCP significantly decreases the activity of Pd black toward formic acid oxidation, which can be resumed after a short positive potential pulse to activate CO oxidation (Fig.1). *In situ* ATR-IR spectroscopy enables to correlate the electrocatalytic performances of pristine and dealloyed Pd-Ni-P nanofilms toward EOR<sup>[4]</sup>. In response to the significantly enhanced oxidation current over time on the dealloyed nanofilm is the increased spectral intensities of interfacial species (such as CO and acetate that are respectively involved in the C1 and C2 pathways of EOR, not shown). In addition, the spectral results indicate that relative contribution of the C1 pathway to the C2 pathway increases on the dealloyed nanofilm as compared to that on the pristine one.

**Fig. 1** (A) Chronoamperometric curves for the Pd black/Au electrode in 5 M FA + 0.1 M HClO<sub>4</sub> solution for two potentiodynamic measurements between 0.1 and 0.5 V at 10 mV s<sup>-1</sup> before and after reactivation at 1.3 V (RHE). (B) Corresponding time-evolved IR spectra in the two runs of potentiodynamic measurements.

**Acknowledgements:** Financial supports from NSFC (grant No. 21273046 and 21473039) and SMCS (grant NO.11JC140200) are highly appreciated.

# Three Dimensional Precious Metal Free Electrocatalysts for Water Splitting

Chuan Zhao, Xunyu Lu, Changlong Xiao  
School of Chemistry, The University of New South Wales  
Kensington Campus, Sydney, New South Wales, 2052  
chuan.zhao@unsw.edu.au

In an electrolytic water splitting cell, the production of H<sub>2</sub> at the cathode is severely constrained by the sluggish kinetics of the oxygen evolution reaction (OER) on the anode. As a consequence, highly efficient OER catalysts are required to lower the energy barrier to improve the overall energy efficiency. So far, IrO<sub>2</sub> and RuO<sub>2</sub> are the benchmark OER catalysts, owing to their high catalytic activity. Nevertheless, these precious metals are costly and their supply is not sustainable, therefore are not suitable for large-scale applications. Hence, enormous research efforts have been devoted to the development of low cost OER electrocatalysts based on first-row transition metals and their oxides, which exhibit good OER activity with significantly lowered fabrication costs.<sup>1,2</sup> Among these catalysts, nickel and cobalt based composites have shown promise as active catalyst materials for OER, which usually require overpotentials around 350 ~ 450 mV to deliver a current density (*j*) of 10 mA cm<sup>-2</sup>. Nevertheless, effective strategies are desired to further enhance the OER activity of the transition metal based catalysts to a level that is comparable to the benchmark IrO<sub>2</sub> and RuO<sub>2</sub>. Furthermore, to be used for industrial applications, OER catalysts also need to meet more strict criteria such as delivery of very high current densities ( $\geq 500$  mA cm<sup>-2</sup>) at low overpotentials ( $\leq 300$  mV), and mechanical robustness and prolonged durability during strong gas evolution.

The presentation concerns our strategies and progress in enhancing the OER activity of non-precious metal based OER catalysts, including downscaling, and/or making mesoporous structures Co<sub>3</sub>O<sub>4</sub> based OER catalysts,<sup>3,4</sup> using carbon nanomaterials as substrates to immobilize nanoparticle catalysts,<sup>5,6</sup> and making multi-metallic catalysts by taking advantage of synergistic metal-metal interactions.<sup>3,4</sup> Finally, we show a hierarchically structured three-dimensional nickel-iron electrodes fabricated by electrodeposition,<sup>7</sup> which only requires an overpotential of 200 mV to initiate the reaction, and is capable of delivering current densities of 500 and 1000 mA cm<sup>-2</sup> at overpotentials of 240 and 270 mV, respectively. To the best of our knowledge, this is the most efficient oxygen evolution electrode in alkaline electrolytes reported so far.

# Highly Active and Stable Iron-nitrogen-doped Carbon with Hollow-core-mesoporous-shell (HCMS) Structure for Oxygen Reduction Reaction

Ming Zhou, Kwong-Yu Chan\*

The University of Hong Kong

Department of Chemistry, HKU, Pokfulam Road, Hong Kong

\*Email: [hrcscky@hku.hk](mailto:hrcscky@hku.hk)

The electrochemical oxygen reduction reaction (ORR) has been studied for decades in the development of fuel cells and lately for growing interests in rechargeable metal-air batteries and microbial fuel cells. The ORR is actively investigated to overcome the unresolved issues of mass-transport limitation, high costs and degradability of electrocatalysts. Non-precious metal and nitrogen doped carbons have attracted much attention for their low costs, good electrochemical activity, and durability in ORR. With a lattice structure similar to that of graphite, nitrogen doped carbon has high crystallinity and intrinsically limited in microporosity and high surface area. It is desirable to use a hierarchical hollow core-mesoporous shell (HCMS) geometry to create multi-scale porosity and enhance mass transfer of ORR.

Achieving economic and environmental viability of hydrogen production through water splitting using energy derived from sustainable sources is the hallmark of the hydrogen economy. Electrocatalysis of water is possibly the most advanced green means of H<sub>2</sub> production. When coupled to a fuel cell, the produced H<sub>2</sub> can directly be used to generate power at the site of generation thus eliminating geographical constraints to power provision. The state-of-the art catalysts for electrocatalytic water splitting are derived from platinum group metal oxides, typically RuO<sub>2</sub> and IrO<sub>2</sub>, while for fuel cells; it is mainly platinum or its alloys. Although non-precious metal catalysts for both O<sub>2</sub> reduction and water oxidation exists, their notorious instability is by far the single unresolved impediment hampering practical applications. In this presentation, exceptionally active bifunctional catalysts for oxygen electrodes obtained by selective pyrolysis and subsequent mild calcination of cobalt, manganese and nickel N<sub>4</sub>-macrocyclic complexes to form the respective oxides of the metals M<sub>x</sub>O<sub>y</sub> embedded in a porous nitrogen-rich shell will be discussed.<sup>[1]</sup> A second part of the presentation will discuss the design of highly stable and active bifunctional catalysts for reversible oxygen electrodes by oxidative thermal scission, where we concurrently rupture nitrogen-doped carbon nanotubes and oxidize Co and Mn nanoparticles buried inside them to form spinel Mn–Co oxide nanoparticles partially embedded in the nanotubes.<sup>[2]</sup> High dual activity for O<sub>2</sub> reduction and evolution surpassing those of Pt/C, RuO<sub>2</sub>, and IrO<sub>2</sub> is achieved using these catalysts. This raises the prospect of functional low-cost, non-precious-metal bifunctional catalysts in metal–air batteries and reversible fuel cells, among others, for a sustainable and green energy future. The presentation will also cover detailed discussion of the long term stability of the catalysts.

In spite of decades of research, no commercially viable alternative to supported Pt nanoparticles as oxygen reduction reaction (ORR) catalyst at the cathode side of low-temperature polymer electrolyte fuel cells (PEFC) has emerged. Supporting nano-particulate Platinum electrocatalysts on high surface area carbons made the use of Platinum-Group-Metals (PGMs) viable from a cost perspective. It has, however, become clear that the stability of carbon supports is compromised under common PEFC operating conditions, making carbon corrosion one of the lifetime determining degradation processes. Using a small number of thermodynamically stable oxides, improved stability towards cycling could be demonstrated in recent years [1].

The impact of radically changing the physical nature of the support from carbon to oxide on electrocatalytic properties of the supported electrocatalyst remains a topic of great interest. Strong Metal-Support Interactions (SMSI), influencing the catalytic activity of Pt nanoparticles, are well known in heterogeneous catalysis [2]. The topic has also gained traction in electrocatalysis in recent years due to an increased research focus on non-carbon supports. Experiments have revealed an influence of the metal oxide type and the metal oxide surface stoichiometry on the stability and the activity of the supported Pt particles [3,4]. So far, however, the precise theoretical understanding of the origin of these metal-support interactions remained deficient.

We present results from a theoretical study of metal-support interactions, focusing on electronic effects. Using Density-Functional-Theory (DFT), we investigated Pt<sub>55</sub> clusters supported on various SnO<sub>2</sub>-type supports: Undoped SnO<sub>2</sub> slabs as well as Sb-doped and In-doped ones with both stoichiometric and reduced (110) surfaces were used in the study. We followed an approach to identify purely electronic interactions between the Pt clusters and the support oxide by excluding lattice relaxation effects in the calculation of the combined system of Pt cluster and support. We relate our results to a more fundamental understanding of electronic metal-support interactions in terms of thermodynamic equilibration of the electron systems in the support oxide and the Pt nanoparticles. The possible influence of the observed interactions on the catalytic activity towards ORR was quantified by calculating the changes in the binding energy of an oxygen adatom on the outer surface of the Pt nanoparticle. The resultant order of magnitude of the influence of electronic metal-support interactions on the catalytic ORR activity is in agreement with recent experimental findings for Pt nanoparticles supported on oxidized and on reduced SnO<sub>2</sub> thin-film surfaces [4].

# Microscopic and Electrochemical Signatures of Copper-poly(propyleneimine) Metallodendrimer System

Candice Rassie, Lindsay Wilson, Prof. Priscilla Baker, Prof. Emmanuel Iwuoha  
Sensorlab, Department of Chemistry, University of the Western Cape  
Robert Sobukwe Road, Bellville, 7535, Cape Town, South Africa  
[2734778@myuwc.ac.za](mailto:2734778@myuwc.ac.za) and [eiwuoha@uwc.ac.za](mailto:eiwuoha@uwc.ac.za)

Metallodendrimers are synthetic, highly branched macromolecules which incorporate a metallic center, thereby improving the molecules catalytic behaviour[1]. These macromolecules have been proven to have many applications, one of which is its electrocatalytic behavior as a platform for electrochemical biosensors [2]. The objective of this work is to study the electrochemical characteristics as well as the morphology of a first generation poly(propyleneimine) based copper functionalized metallodendrimer (CuPPI), for its application in electrochemical biosensing. The CuPPI metallodendrimer was physically adsorbed onto the surface of a gold (Au) electrode to form an Au|CuPPI electrode system, which was then electrochemically characterized by cyclic and square wave voltammetric techniques. The electrochemical characterization reveals primary anodic and cathodic peaks at  $E_{pa} = 220\text{mV}$  and  $E_{pc} = 180\text{mV}$  respectively, along with secondary peaks which represent a cascade reaction occurring within the dendritic structure. These primary peaks are attributed to the oxidation of the reduced form of Cu(I) to Cu(II) and its subsequent reduction back to Cu(I). The CuPPI metallodendrimer was found to be electroactive on Au electrode and has diffusion coefficient (D) values of  $4.124 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$  (in the absence) and  $3.29 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$  (in the presence) of oxygen in the cell solution. The surface morphology of the poly(propyleneimine) dendrimer (PPI) and its copper-functionalized derivative, i.e. CuPPI, were compared using atomic force microscopy (AFM). High resolution transmission electron microscopy (HR-TEM) and high resolution scanning electron microscopy (HR-SEM), as shown in **figure 1** below reveals that CuPPI has a layered crystalline structure. The metallodendrimer would be a suitable platform for electrochemical biosensing applications since the diffusion coefficient is only very slightly affected by the presence of oxygen. The layered structure afforded a suitable enhancement in surface area for the immobilization of biological molecules such as enzymes. The metallodendrimer was used as an electrocatalytic platform for the determination of a TB patient's metabolic profile towards various TB drugs such as isoniazid and ethambutol.

# Heat-treated 3,5-diamino-1,2,4-triazole/graphene Hybrid Functions as an Oxygen Reduction Electrocatalyst with High Activity and Stability

Hiroyuki Koshikawa, Kazuhide Kamiya, Shuji Nakanishi, Kazuhito Hashimoto  
 Department of Applied Chemistry, The University of Tokyo  
 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan  
 kamiya@light.t.u-tokyo.ac.jp

Electrochemical oxygen reduction reaction (ORR) is important as a cathode reaction of various types of fuel cells. Thus, development of electrocatalysts composed only of abundant elements is strongly required. In natural systems, multi-copper (Cu) oxidases, such as laccase and bilirubin oxidase, catalyze the four-electron ORR for respiration with lower over-potential than Pt in neutral pH conditions.<sup>1)</sup> In these enzymes, modulation of the electronic state and molecular structures of the atomic Cu centers through coordination with amino acid residues is believed to be essential for their high catalytic activities.<sup>2)</sup> For this reason, numerous studies have been conducted to synthesize Cu-N complexes by mimicking the coordination structure of those enzymes. For example, a copper complex of 3,5-diamino-1,2,4-triazole (Cu-DAT) supported on carbon black exhibited an onset potential of 0.73 V (vs. RHE) at pH 7 for the ORR, which is the highest value among Cu-based catalysts reported to date.<sup>3)</sup> However, the weakness of molecular catalysts caused by decomposition of organic ligands is the major obstacle for their application. We recently reported that stable graphene materials with iron (Fe)-N coordination bonds can be synthesized by the short-duration heat treatment (< 60 s) of graphene oxides (GO) in the presence of an Fe-N complex, and the resulting catalyst exhibited both the high activity and stability of the ORR.<sup>4)</sup> Therefore, it is worth investigating whether this synthesis method can be applied to Cu-DAT to enhance its robustness.

The heat-treated catalyst (HT/Cu-DAT) was synthesized by heating Cu-DAT in the presence of GO at 900 °C for 45 s. The Cu-DAT complex supported on a carbon black (non-HT/Cu-DAT) was prepared as described in the previous paper.<sup>3)</sup> ORR activities were evaluated using a rotating ring-disk electrode (RRDE) in a 0.1 M phosphate-buffer solution (pH 7.0). Elemental and structural analysis were performed by X-ray photoelectron spectrometry (XPS) and extended X-ray absorption fine structure (EXAFS) analyses.

Fig. 1 shows the  $j$  vs.  $U$  curves for HT/Cu-DAT and non-HT/Cu-DAT in the presence of oxygen. HT/Cu-DAT generated a cathodic current with an onset potential of 0.79 V (vs. RHE) and exhibited the ORR catalytic activity comparable to that of non-HT/Cu-DAT. To our knowledge, the onset potential of HT/Cu-DAT is the highest value reported to date among Cu-based ORR catalysts in neutral solution.<sup>5)</sup> To evaluate the stability, 1000 cycles of CV were conducted for both catalysts. Although the absolute current density value at 0.6 V (vs. RHE) after the CV cycling decreased by 77% for non-HT/Cu-DAT, it decreased only by 22% for HT/Cu-DAT. These results indicated that the stability of HT/Cu-DAT was enhanced by the heat treatment. The XPS and EXAFS results suggested that N atoms coordinated to Cu atoms were doped into the graphene network during the heat treatment for HT/Cu-DAT (Fig. 2(a)), leading to the improved stability of the catalyst. In contrast, Cu-DAT was only physically adsorbed onto the carbon black particles in non-HT/Cu-DAT (Fig. 2(b)).

# Electrochemical Responses of Transglutaminase Immunosensor Developed on a Polypyrrole-Cobalt (II) Salicyladiimine Dendritic Composite Material

Lindsay Wilson, Candice Rassie, Prof. P. Baker, Prof. E. Iwuoha  
SensorLab, Department of Chemistry, University of the Western Cape,  
Robert Sobukwe Road, Bellville, 7535, Cape Town, Republic of South Africa  
[2724554@myuwc.ac.za](mailto:2724554@myuwc.ac.za) and [eiwuoha@uwc.ac.za](mailto:eiwuoha@uwc.ac.za)

Transglutaminase (tTG), a calcium dependent enzyme catalysis protein cross linkages such as glutamine to the lysine on proteins. Transglutaminase exhibits high specificity towards glutamine substrates and forms an enzyme complex with gliadin that produces an immune response against this complex [1-2]. This immune response resulted in the identification of transglutaminase as the auto antigen of celiac disease. Since transglutaminase is predominantly involved in the activation and progression of celiac disease, it results in the production of antibodies against it. This then results in the harmful damage to the small intestine which reduces food digestion diffusion into the blood vessels [3]. The standard diagnosis of celiac disease is tedious and expensive. The diagnosis of coeliac disease can be done by the measurement of antibodies against transglutaminase [4]. In this work, an electrochemical impedimetric immunosensor was developed for the detection of anti-transglutaminase antibodies. The immunosensor consisted of a polypyrrole-cobalt (II) salicyladiimine metallodendrimer composite on a platinum electrode with transglutaminase as the recognition element. Atomic force microscopy was used to determine surface roughness of the modified platinum electrode with values of 879.24 nm, 76.55 nm and 364.27 nm for polypyrrole, cobalt (II) salicyladiimine and their respective composite. The composite provided a suitable micro-environment for monitoring antibody-antigen interactions in conjunction with their cyclic voltammetry. Electrochemical impedance spectroscopy parameters such as exchange current and heterogeneous rate constant are used to evaluate immunosensor where the rate constants were  $2.7 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ ,  $4.6 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$  and  $4.16 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$  for cobalt (II) salicyladiimine metallodendrimer, polypyrrole and their composite. Impedimetric detection of anti-transglutaminase antibody gave a limit of detection of 201 ng/mL and linear range of  $10^{-5}$  -  $10^{-4}$  mg/mL with correlation coefficient of 0.948.

Figure 1. Nyquist plot for anti-tTG antibody incubation at, (a)  $2.85 \times 10^{-4}$  mg/mL, (b)  $5.7 \times 10^{-4}$  mg/mL, (c)  $8.55 \times 10^{-4}$  mg/mL, (d)  $11.4 \times 10^{-4}$  mg/mL, (e)  $14.25 \times 10^{-4}$  mg/mL, (f)  $17.1 \times 10^{-4}$  mg/mL and calibration graph for immunosensor  $R_{ct}$  versus anti-tTG antibody concentration in 0.1 M phosphate buffer. B) Calibration plot for the detection of anti-tTG antibody in 0.1 phosphate buffer.

# Novel Structured Pt-Based Intermetallic Electrocatalysts for ORR

Deli Wang, Jing Zhu, Sufen Liu, Jie Wang, Zexing Wu

*School of Chemistry & Chemical Engineering, Huazhong University of Science & Technology  
1037 Luoyu Road, Wuhan, China  
wangdl81125@hust.edu.cn*

The rational synthesis of active, durable, and low-cost catalysts is of particular interest to fuel cell applications. Pt is a key element in both anode and cathode of fuel cells. However, Pt is currently costly and scarce, it poses a question of how to lower the Pt loading and increase the efficiency. Most of previous studies focused on Pt alloyed with some 3d-transition metals, such as Fe, Co, Ni, etc. The activity and stability need to be further improved for fuel cell applications. To enhance and optimize the performance and durability of Pt for the oxygen reduction reaction, we look beyond Pt-metal disordered alloys and describe a new class of Pt-based ordered structured intermetallic nanoparticles for the oxygen reduction reaction. In our studies, we found that carbon supported Pt<sub>3</sub>Co and PtCu<sub>3</sub> ordered intermetallic nanoparticles can be easily formed using a simple impregnation-reduction method followed by high temperature pretreatment. Ordered Pt<sub>3</sub>Co intermetallic cores with a 2-3 atomic-layer thick platinum-rich shell showed over 200% increase in mass activity and over 300% increase in the specific activity compared with the disordered Pt<sub>3</sub>Co alloy nanoparticles for the ORR. Electrochemical and chemical dealloying methods were implemented on Cu<sub>3</sub>Pt/C nanoparticles to control the atomic-level morphology and activating the performance for oxygen reduction reaction (ORR). It is found that by controlling electrochemical dealloying parameters resulted in different morphology, while the chemical leaching gave rise to a spongy structure. Both dealloying methods yielded enhanced specific and mass activity for ORR and higher stability relative to Pt/C. These findings are important to build next-generation fuel cell catalysts.

# Facile synthesis of starch-scaffolded bimetallic Au-Pt nanostructure and electrocatalysis

Christian Engelbrekt, Nedjeljko Seselj, Jens Ulstrup, Jingdong Zhang\*

Department of Chemistry, Technical University of Denmark, 2800 Kgs. Lyngby, Denmark.

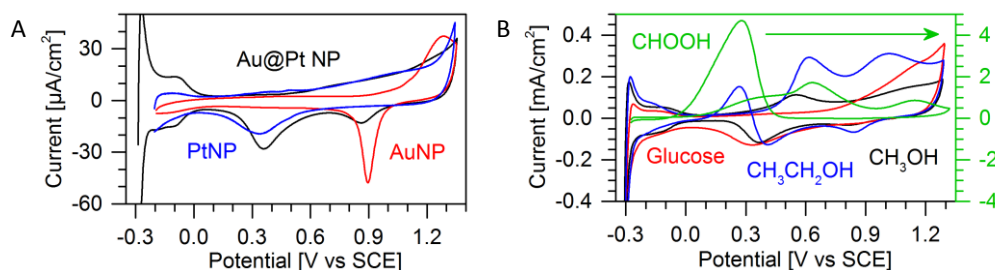

[cheng@kemi.dtu.dk](mailto:cheng@kemi.dtu.dk), [jz@kemi.dtu.dk](mailto:jz@kemi.dtu.dk)\*

A facile, one-pot synthesis procedure has been developed for the preparation of two types of bimetallic Au-Pt nanostructures. By controlling the timing and conditions of the syntheses, gold nanoparticle (AuNP) cores (1) with an atomically thin platinum shell nanoparticles, and (2) encapsulated in a porous network of 2-3 nm platinum nanoparticles (PtNPs) can be prepared, denoted Au@Pt NPs and nanoflowers (NFs), respectively.

**Figure 1.** Transmission electron micrographs of (A) Au-Pt core-shell NPs, Au@Pt NPs and (B) Au cores encapsulated by a porous network of 2-3 nm PtNPs.

The exact concentration of Pt precursor and the dynamics of its reduction are critical for core-shell formation as rapid precursor reduction leads to unwanted nucleation of PtNPs. Formation of an atomically thin Pt shell leads to a drastic change in optical properties. The localized surface plasmon resonance (LSPR) of the Au core is almost completely dampened and the colloid changes color from red to brown. Meanwhile, no significant change in particle size is detectable by transmission electron microscopy (TEM). Electrochemical characterization of the Au@Pt NPs reveals a large Pt response confirming the formation of a core-shell structure.

**Figure 2.** (A) Cyclic voltammograms of Au@Pt NPs, AuNPs and PtNPs on glassy carbon electrode (GCE) in 0.1 M  $\text{H}_2\text{SO}_4$ . (B) Cyclic voltammograms of Au@Pt NPs on GCE in 0.1 M  $\text{H}_2\text{SO}_4$  with 0.1 M methanol, glucose, ethanol or formic acid. Scan rate is 50 mW/s in all cases.

The as-synthesized Au@Pt NPs were tested as catalysts for electrocatalytic oxidation of small organic fuel molecules, i.e. methanol, ethanol and formic acid. Especially promising results were obtained for formic acid oxidation during which the Au@Pt NPs showed good resistance towards poisoning.

The AuNP core size can be controlled through a seeded growth approach from 8 to 80 nm. Varying the reaction conditions during shell synthesis enabled the formation of a porous network of individual 2-3 nm PtNPs surrounding a single AuNP core rather than the thin shell deposited directly on the AuNP. Nanoflowers with PtNP network shells from a few nm to more than 100 nm were prepared.

## Effect of Iron Precursor on Oxygen Reduction Reaction of Fe-N-C Catalyst in PEMFC

Vuri Ayu Setyowati, Hsin-Chih Huang, Chen-Hao Wang\*

*Department of Materials Science and Engineering, National Taiwan University of Science and Technology, 10607, Taipei, Taiwan.*

\*chwang@mail.ntust.edu.tw

The non-precious metal catalyst by using transition metal with nitrogen-doped carbon material shows the good activity of oxygen reduction reaction (ORR), which has the opportunity to replace the high-cost platinum catalyst in the proton exchange membrane fuel cell (PEMFC) in the recent studies [1-3]. In this study, various iron precursors were chose to mix with polyaniline and carbon black (XC-72), and subsequently the mixture was introduced to the furnace for the pyrolysis. For the preparation of Fe-N-C catalyst, the ratio of polyaniline and XC72 was 1:1, the Fe content was fixed to 7 wt.% for the preparation of Fe-N-C catalyst. The electrochemical analysis shows that  $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$  mixed with polyaniline are the preferred iron precursor ( $\text{FeCl}_3\text{-PANI-C}$ ) to get higher ORR activity than the others, which its electron-transfer number is around 3.99. The Raman spectrum of  $\text{FeCl}_3\text{-PANI-C}$  shows the ratio of G-band and D band ( $I_G/I_D$ ) corresponding to the degree of graphitization. The higher activity of catalyst has the lower  $I_G/I_D$  on Raman spectra due to high nitrogen functionalities content [4]. The ratio between C/N/O is determined by XPS spectra, showing the high ratio of N element of  $\text{FeCl}_3\text{-PANI-C}$ . The N composition is consisted of pyrrolic N, cyanide, and quaternary N. The major N composition of  $\text{FeCl}_3\text{-PANI-C}$  is quaternary N about 57.73%. XANES spectra of  $\text{FeCl}_3\text{-PANI-C}$  shows that the oxidation state of central Fe is 3+ and the changing of coordination structure occurs after pyrolysis. The stability tests of  $\text{FeCl}_3\text{-PANI-C}$  shows only 50mV decay after 30000 cycle times.

# Size, Shape and Morphology Effects on Catalytic Activity of Oxygen Reduction Reaction

Minhua Shao

*Department of Chemical and Biomolecular Engineering, Hong Kong University of Science and Technology, Kowloon, Hong Kong  
kemshao@ust.hk*

Low temperature fuel cells are electrochemical devices that convert chemical energy directly to electricity. They have great potential for both stationary and transportation applications and are expected to help address the energy and environmental problems that have become prevalent in our society. Despite their great promise, commercialization has been hindered by lower than predicted efficiencies and the high cost of Pt-based electrocatalysts in the electrodes. For more than five decades, the predominant work has been focused on the development of novel catalysts for the cathodic reaction (oxygen reduction reaction), which has sluggish kinetics and is responsible for the high overpotential. Recent intensive research efforts have led to the development of less expensive and more abundant materials for fuel cells, such as non-precious metal catalysts, metal oxides/carbides, and precious metal alloys.

In this talk, I will present recent progress in developing advanced catalysts for oxygen reduction reaction in my group, with an emphasis on core-shell and shape controlled Pt- and Pd-based nanocrystals. The composition, morphology and size effects on the catalytic activities will be explored. The mechanisms for activity enhancement will also be discussed based on the results of density functional theory (DFT) calculations.

Pt-based materials are widely used as electrocatalysts for oxygen reduction reaction (ORR). However, the high cost will hinder the development of fuel cells. Consequently, great efforts on non-precious metal catalysts (NPMCs) have been investigated extensively, and nitrogen-containing catalyst is considered as the most promising candidate due to its high activity, remarkable performance stability [1-2].

In this work, Fe-N-C electrocatalyst with excellent performances was prepared via one-step heat-treatment method using riboflavin as nitrogen and carbon source, and ferric chloride as transition metal precursor. This approach has the advantages of cheap and nontoxic precursors, simple process, and easy scale-up. The ORR activity and stability of catalyst were characterized by linear sweep voltammetry (LSV) and chronoamperometry in 0.5 M H<sub>2</sub>SO<sub>4</sub> solution. Effects of heat-treatment temperature and Fe contents were investigated. The catalyst prepared with Fe content of 7 wt% and heat-treated at 800 °C exhibits the highest ORR activity. The LSV curves before and after 1000 cycles are shown in **Fig. 1** (Middle), the performance decay is negligible above 0.3 V; the chronoamperometric response at 0.3 V (vs Ag/AgCl) is shown in **Fig. 1** (Right), the catalyst activity keeps more than 93% of the initial activity after 10800s. All of these indicate the stability of catalyst is excellent.

**Fig.1** LSV curves of Fe-N-C catalysts prepared at various heat-treatment temperatures (Left), before and after 1000 cycles (Middle) and Chronoamperometric response at 0.30 V (vs Ag/AgCl) (Right) in O<sub>2</sub> saturated 0.5 M H<sub>2</sub>SO<sub>4</sub> solution at room temperature.

# Pt<sub>3</sub>Ni intermetallic with Pt-rich surface supported on porous carbon as a high efficient electrocatalyst for oxygen reduction reaction

Bin-Wei Zhang, Yan-Xia Jiang, Shi-Gang Sun

State Key Laboratory of Physical Chemistry of Solid Surfaces, Department of Chemistry, College of Chemistry and Chemical Engineering, Xiamen University  
Xiamen 361005, (P. R. China)  
yxjiang@xmu.edu.cn

The slow rate of the oxygen reduction reaction (ORR) at the cathode is one of the main challenges for the development of polymer electrolyte membrane fuel cells (PEMFCs). Commercial ORR catalysts is generally Pt-based catalysts, however, the high cost and scarcity of Pt are the key obstacles for its broad deployment in fuel cells. Recently, it is of great interest to explore more active catalysts, with superior performance and durability, than the traditionally employed carbon-supported Pt (Pt/C) nanoparticles. To achieve this target, the Pt-base bi- and tri-metallic electrocatalysts, such as alloying Pt with the 3d-transition metals (Fe, Co, Ni), have been rationally synthesized and shown with greatly enhanced activities for the ORR. Vojislav et al [1] found that the Pt<sub>3</sub>Ni(111) with its outermost is Pt-rich, is more active for ORR than the Pt(111) and more active than Pt/C. In this work, we developed a simple and novel method to synthesis the Pt<sub>3</sub>Ni with Pt-rich surface in the porous graphitic carbon (Pt<sub>3</sub>Ni/PC), in which controlled thermal treatment of the precursor of Pt and Ni formed the desired Pt-rich surface. The method can be readily scaled up to produce high-performance electrocatalysts with the Pt-rich structure, and importantly it can be generalized toward the design of other multimetallic systems.

Figure 1 The TEM images of PC (A) and Pt<sub>3</sub>Ni/PC (B), and (C) ORR polarization curves for Pt/C and Pt<sub>3</sub>Ni/PC in O<sub>2</sub>-saturated 0.1 M HClO<sub>4</sub> at room temperature; 1,600 rpm and 10 mV s<sup>-1</sup> of sweep rate. The insert in (C) shows the model of Pt<sub>3</sub>Ni/PC.

TEM image of porous graphitic carbon is shown in Figure 1A, which shows the morphology of PC and confirms that PC is porous graphitic carbon. TEM image of Pt<sub>3</sub>Ni/PC is shown in Figure 1B, clearly demonstrated that the Pt<sub>3</sub>Ni nanoparticles with well dispersed and high loaded in the PC. The size of the Pt<sub>3</sub>Ni nanoparticles was measured from 200 nanoparticles in the TEM images of Pt<sub>3</sub>Ni/PC, and it was determined to be  $3.87 \pm 1.24$  nm for Pt<sub>3</sub>Ni/PC. The polarization curves for the ORR on Pt/C and Pt<sub>3</sub>Ni/PC in an O<sub>2</sub>-saturated 0.1 M HClO<sub>4</sub> solution are shown in Figure 1C. For two catalysts, the diffusion-limiting currents were obtained to be  $\sim 5.6$  mA cm<sup>-2</sup>. And the mixed kinetic-diffusion control region occurs between 0.6 V and 1.0 V, in this region, the half-wave potential of an ORR polarization curve,  $E_{1/2}$ , is often used to evaluate the electrocatalytic activity of a catalyst. The  $E_{1/2}$  was respectively 0.841 and 0.905 V in Pt/C and Pt<sub>3</sub>Ni/PC, and it showed a marked positive shift of 64 mV on Pt<sub>3</sub>Ni/PC related to Pt/C. The Pt<sub>3</sub>Ni/PC exhibited a mass activity of 0.69 mA/μgPt on the basis of the total mass of Pt at 0.9 V versus a reversible hydrogen electrode (RHE), which was 3.8 times greater than that of the Pt/C catalyst (0.18 mA/μgPt).

This work was supported by National Science Foundation of China (Grant No. 21273180).

# Supersaturation Dependent Evolution of Nanocrystal Surfaces and its Application in the Synthesis of Noble Metal Nanocatalysts with Enhanced Electrocatalytic Properties

Zhaoxiong Xie, Qiaoli Chen, Haixin Lin, Yanyan Jia, Zhenming Cao, Yaqi Jiang, Lansun Zheng  
*State Key Laboratory of Physical Chemistry of Solid Surfaces, Collaborative Innovation Center of Chemistry for Energy Materials, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen, Fujian, China*  
*e-mail: zxxie@xmu.edu.cn*

Many physical and chemical properties of crystals depend on the surface structures because of the anisotropic properties of crystal. In past several decades, surface chemists have acquired great achievements on the studies of surface structure dependent properties by applying bulk single crystals. However, in many applied fields, such as catalysis, nanocrystals are concerned. It is therefore very important to achieve nanocrystals with different crystal surface. In recent years, numerous efforts have been paid to the control of surface structure, it is still extremely difficult to predict or design the surface structure of micro-/nano- crystals. General methods for the control of the exposed crystal face are still lack.

Based on thermodynamics, we reason that the surface energy of the exposed facets is direct proportional to the supersaturation of the growth units in the growth medium during the crystal growth (Thomson-Gibbs equation):

$$\Delta G = \mu_l dn_l + \mu_c dn_c + \sigma dS = 0$$

$$\Delta\mu = \mu_l - \mu_c = \frac{2\sigma v}{h}$$

According to this theory, we successfully designed and achieved surface structure evolution of some ionic crystals, molecular crystals by controlling the supersaturation during the crystal growth process. It has been found the surface energies of nanocrystals increase with the increase of supersaturation of crystal growth unit.

As has been known, nanocrystals with exposed high-energy crystal facets usually show better electrocatalytic activities, due to abundant unsaturated coordination atoms and atomic steps and ledges. However, in order to minimize the surface energy of the crystals, the high-energy facets quickly disappeared in the crystal growth process. By understanding the crystal growth habit under the nonequilibrium (supersaturated) condition, it is easy to control the nanocrystal crystal surfaces with high surface energy. For example, we synthesized Au nanocrystals exposed by different surface (such as (111), (100), (221), and (110)) by simply regulating reduction rate of metal precursor, by which the supersaturation of metal crystal growth unit were tuned. In addition, Pd, Pd-Au alloy nanocrystals with enhanced electrocatalytic properties have also been successfully synthesized.

# Exploration of efficient low-platinum and non-platinum catalysts for oxygen reduction reaction

## Symposium 9: Electrocatalytic Materials

Meiling Xiao, Jianbing Zhu, Junjie Ge, Changpeng Liu and Wei Xing\*  
Changchun Institute of Applied Chemistry, Chinese Academic of Sciences  
Renmin Street 5625, Changchun, Jilin  
xingwei@ciac.ac.cn

Electrochemical oxygen reduction is a critical process for many energy storage and conversion devices. Although Pt and Pt-based alloys have proven to be the most efficient catalysts for ORR, the high cost and limited reserve of Pt significantly hinder their large-scale applications. Additionally, the Pt and Pt-based catalysts undergo degradation during long-term electrochemical operation. Great efforts have been devoted to search for effective and stable catalysts with decreased Pt loading and even non-platinum catalysts. Our recent work is associated with the advance in this research field. For the design of low-platinum catalysts, strongly coupled platinum nanotubes and nitrogen-doped graphene was synthesized by in-situ galvanic replacement reaction. This novel-structured catalysts exhibited higher activity and durability than the commercial Pt/C catalyst, with a mass activity of 0.35 A mg<sup>-1</sup><sub>Pt</sub> at 0.9 V, 1.69 times higher than commercial Pt/C (0.13 A mg<sup>-1</sup><sub>Pt</sub> at 0.9 V). For the exploration of non-platinum catalysts, meso/macroporous nitrogen-doped carbon architectures with iron carbide encapsulated in graphitic layers were fabricated by pyrolysing of polymers and iron sources. Electrochemical analysis revealed that this carbon-based material with well-designed pore structure can be promising alternatives to platinum for oxygen reduction reaction in both acidic and alkaline solutions.

Oxygen evolution reaction (OER) is one of the paramount steps in sustainable energy conversion and storage technologies.<sup>1-3</sup> Spinel oxide Co<sub>3</sub>O<sub>4</sub> has long been recognized as a promising alternative non-precious OER electrocatalyst for its good activity and low cost. Numerous nanostructured Co<sub>3</sub>O<sub>4</sub> materials have been developed in order to acquire better OER performance.<sup>4-6</sup> Herein, we have adopted thermal H<sub>2</sub> annealing and air exposure to modify the surfaces of crystalline Co<sub>3</sub>O<sub>4</sub>. Our results demonstrate the remarkably enhanced OER activity of the surface modified Co<sub>3</sub>O<sub>4</sub> electrocatalyst despite its increased crystal size and reduced surface area. The improved OER performance is believed to be relevant to the surface amorphous layer consisting of hydrated cobalt (oxy)hydroxide species on the reduced Co<sub>3</sub>O<sub>4</sub>.

# Catalyst Layer Structures for Enhancement of Redox Reactions of Oxovanadium Ions

Jun Maruyama<sup>a</sup>, Tsutomu Shinagawa<sup>b</sup>

<sup>a</sup>Environmental Technology Research Division, <sup>b</sup>Electronic Material Research Division, Osaka Municipal Technical Research Institute, 1-6-50, Morinomiya, Joto-ku, Osaka 536-8553, Japan  
maruyama@omtri.or.jp

Vanadium redox flow batteries (VRFBs) have attracted much interest as a promising electrical energy storage system due to their suitability for large-scale energy storage and capability to withstand fluctuating power supplies. The slow reaction rate of the electrode reactions is a serious problem in VRFB technology, which has to be overcome to improve the efficiency of the VRFB. Recently, the high catalytic activity was found at a carbonaceous thin film with Fe and four nitrogens (Fe-N<sub>4</sub> site) combined in a carbon matrix in the square-planar configuration and exposed to the surface [1]. The carbonaceous thin film was supported on cup-stack carbon nanotube (CSCNT). In this study, the structure modification of the catalyst layer formed from the thin-film coated CSCNT was attempted for the enhancement of the VRFB positive electrode reactions

The 1:10 weight ratio mixture of iron phthalocyanine (FePc) powder and CSCNT was put in a crucible with a cap and heat-treated at 800 °C after raising the temperature at 1 °C min<sup>-1</sup> in an argon atmosphere. A treatment with an acid solution was carried out to remove any soluble metallic species from the surface. The obtained sample was then labeled CFePc01-800. An aliquot of 5 mg of CFePc01-800 was added to the mixture of 0.5×*x* (*x* = 0.1, 0.2, 0.5, 1) cm<sup>3</sup> of 5 wt % Nafion solution and 0.5×(1−*x*) cm<sup>3</sup> of high-purity water, which was then ultrasonically dispersed to produce a catalyst paste, pipetted on a glassy carbon rotating disk electrode (GC RDE), and dried overnight to form the catalyst layers, CFePc01-800-Naf*x*. The catalyst layer was similarly formed using CSCNT at *x* = 1. Aliquots of 5 mm<sup>3</sup> of 4 M NaOH and *y* (*y* = 5, 10, 15) mg of MgO nanoparticles was added to the catalyst paste of *x* = 0.5. After similarly pipetting and drying it, MgO was removed by an HCl treatment to form the catalyst layer, CFePc01-800-Naf*x*-MgO*y*.

Figure 1 shows the relationships between the electrode potential and the current for the VO<sub>2</sub><sup>+</sup> reduction and VO<sup>2+</sup> oxidation. A small current was observed for GC without any catalyst loading (bare GC). The CSCNT loading increased the current, in particular, for the VO<sup>2+</sup> oxidation. The higher VO<sub>2</sub><sup>+</sup> reduction current was observed for CFePc01-800 than that for CSCNT, which was due to the catalysis of the Fe-N<sub>4</sub> structure. The reduction current was dependent on *x* and the substantial increase was attained at *x* = 0.5. This dependency was attributed to two conflicting factors: the decreases in the diffusion resistance by the Nafion phase and the extent of dispersion of CFePc01-800 in the catalyst paste with a decrease in *x*. The addition of MgO nanoparticles to the catalyst paste was efficient to further enhance both VO<sub>2</sub><sup>+</sup> reduction and VO<sup>2+</sup> oxidation currents. The diffusion of the ions was enhanced through the pores formed by the MgO nanoparticles functioning as the template.

Fig. 1. Relationships between electrode potential and current measured in Ar-saturated VO<sub>2</sub><sup>+</sup>(5 mM)–VO<sup>2+</sup>(5 mM)–H<sub>2</sub>SO<sub>4</sub>(1 M) at 25 °C for bare GC and catalyst layers formed from CSCNT, and CFePc01-800 with various amount of (a) Nafion, (b) Nafion and MgO. The MgO particles were removed after the catalyst layer formation. The amount of the sample fixed on the electrode was 20 μg. The geometric electrode surface area was 0.071 cm<sup>2</sup>. The potential scan rate was 10 mVs<sup>-1</sup>. The rotation rate of the electrode was 2000 rpm. The sign of the oxidation (anodic) current was taken as positive.

# Electroreduction of Oxygen with Brominated Metallo-Corroles

Lior Elbaz\*, Naomi Levi

Bar-Ilan University, 1 Max and Ana Webb St.  
Ramat-Gan 52900, Israel  
\*lior.elbaz@hotmail.com

Zeev Gross, Atif Mahammed  
Technion, Haifa 32000, Israel

Fuel cell technology raised new interest over the past two decades due to the increasing oil prices, non-sustainability of fossil fuel and the consequences of combustion on air pollution and climate changes. Two aspects limit the practicality and energy conversion efficiency in polymer electrolyte membrane fuel cells: the rate-limiting oxygen reduction reaction at the cathode and the low abundance and high cost of platinum, which still remains the most efficient catalyst.

Significant effort has been made to develop alternative non-precious metal catalysts (NPMCs) for oxygen reduction. Many of those catalysts have been inspired by biological processes in that their active centers consist of transition metal complexes such as metallo-porphyrins. So far, studies conducted with such catalysts show that their activity and stability is lower than that of the state-of-the-art platinum based catalysts. In most recent years a new class of NPMCs has shown great promise; the metallo-corroles.

A series of first row transition metal  $\beta$ -pyrrole-brominated 5,10,15-tris(penta-fluoro phenyl) - Corroles [M(tpfc)Br<sub>3</sub>, M=Mn, Fe, Co, Ni and Cu] were synthesized and tested as catalysts for oxygen reduction in acidic aqueous solutions. Both the reduced form and the oxidized forms of these corroles were characterized by means of NMR, EPR and UV-vis measurements. Rotating Ring-Disk electrode (RRDE) was used to test the kinetic performance of these corroles in the catalytic reaction of oxygen reduction (ORR). The corroles were adsorbed on a high surface area carbon powder (BP2000) prior to electrochemical measurements, to create a unique composite material. The comparison between the corroles with different metal centers showed a favorable

catalytic performance of the ORR in the case of the Co-Corrole, which showed an onset potential of only 0.8V vs. RHE (Figure 1).

Figure 1: RDE measurements of metallo-corroles at 900 rpm and 5 mV/s in 0.5M H<sub>2</sub>SO<sub>4</sub>

# Platinum-modified Covalent Triazine Frameworks as Methanol-tolerant Oxygen Reduction Electrocatalysts

Kazuhide Kamiya<sup>1</sup>, Ryo Kamai<sup>2</sup>, Kazuhito Hashimoto<sup>1</sup> and Shuji Nakanishi<sup>1</sup>

<sup>1</sup>Department of Applied Chemistry, School of Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan, <sup>2</sup>Research Center for Advanced Science and Technology, The University of Tokyo, 4-6-1 Komaba, Meguro-ku, Tokyo 153-8904, Japan, kamiya@light.t.u-tokyo.ac.jp

Covalent organic frameworks (COFs) are cross-linked porous polymers, which have great potential in catalysis area because of their unique porous structure (i.e. high surface area), mechanical robustness and high design flexibility. Especially, covalent triazine frameworks (CTFs), which have 1,3,5-triazine structure as units, possess the high density of nitrogen (N) atoms in their organic pore, which can strongly immobilize metal centers. Recently, Palkovits *et al.* reported that platinum-modified CTF (Pt-CTF) functioned as a solid catalyst for the selective low-temperature oxidation of methane to methanol [1]. In general, the oxidation of methanol can easily proceed compared to methane oxidation because the C-H bond energy of methanol is much smaller than that of methane. Thus, the catalytic activity for methane partial oxidation to methanol let us assume that Pt-CTF has no activity to oxidize methanol (i.e. methanol tolerance). The methanol tolerance is the essential property for the cathode catalyst of direct methanol fuel cells (DMFC) as the methanol-cross-over effect is one of the issues to be addressed. However, the application of the frameworks as electrocatalysts has not been achieved to date because of their poor electrical conductivity.

In the present work, we have successfully applied CTF-based materials to electrocatalysts by hybridizing non-conductive CTFs with conductive carbon particles (CPs). Specifically, the hybridized material was obtained by the polymerization of CTFs on CPs in molten  $\text{ZnCl}_2$ . Then, Pt atoms were grafted in the pore of CTFs by the impregnated with platinum chloride (Pt-CTF/CP, Figure 1). The resulting catalyst showed apparent electrocatalytic activity for oxygen reduction reaction (ORR). In case of a commercial 20 wt% Pt/C, after the addition of 1 M  $\text{CH}_3\text{OH}$ , the onset potential of the cathodic current shifted approximately 200 mV in the negative direction in the presence of oxygen (Figure 2 inset). In contrast, surprisingly, the overlap of the  $\text{CH}_3\text{OH}$  oxidation current with that of the ORR was almost negligible for Pt-CTF/CP even in the presence of 1 M  $\text{CH}_3\text{OH}$  as shown in Figure 2. These results clearly showed that Pt-CTF/CP exhibited a high methanol tolerance during the ORR, as we expected. This is the first demonstration of the potential for CTF-based materials to serve as electrocatalysts [2].

Figure 1 Schematic illustration of Pt-CTF/CP (gray: N, blue: Pt and brown: C).

Figure 2  $j$  vs.  $U$  curves for Pt-CTF/CP and (inset) 20 wt% Pt/C in 0.5 M  $\text{H}_2\text{SO}_4$  saturated with dissolved oxygen. Methanol concentration: (black) 0 M and (red) 1.0 M.

# Metal-doped Pyrochlore as Novel Anode Material for Intermediate Solid Oxide Fuel Cell

Chien-Yeh Pan, Chia-Kan Hao and Chi-Shen Lee\*

Department of Applied Chemistry, National Chiao Tung University, No. 1001, University Road Hsinchu, Taiwan

Tel: +886-3-5712121#56520; E-mail: chishen@mail.nctu.edu.tw, neilgodiva2008@hotmail.com

## Abstract

In this study, pyrochlore phase  $\text{La}_2(\text{Ce}_{1-x}\text{V}_x)_2\text{O}_{7+\delta}$  ( $x=0.05, 0.1, 0.15, 0.2$ ) and perovskite phase  $\text{La}_{0.8}\text{Sr}_{0.2}\text{Ga}_{0.8}\text{Mg}_{0.2}\text{O}_{3-\delta}$  (LSGM) were synthesized by sol-gel method and used as anode and electrolyte materials for intermediate temperature solid oxide fuel cell (IT-SOFC). These materials were characterized by X-ray diffraction, ICP-AES, SEM-EDS, TPR and EIS. The  $\text{La}_2(\text{Ce}_{0.8}\text{V}_{0.2})_2\text{O}_{7+\delta}$  showed good ionic conductivity and a bottom cell made up of  $\text{La}_2(\text{Ce}_{0.8}\text{V}_{0.2})_2\text{O}_{7+\delta}$  / LSGM/LSCF-GDC (anode/electrolyte/cathode) was fabricated for fuel cell characterization. The as fabricated cell exhibited the optimized power density of  $0.141 \text{ W/cm}^2$  at  $700^\circ\text{C}$ . These results suggested that  $\text{La}_2(\text{Ce}_{0.8}\text{V}_{0.2})_2\text{O}_{7+\delta}$  is a potential anode material for application in IT-SOFC.

# Molybdenum Disulfide/Nitrogen-Doped Graphene Composite as an Electrocatalytic Material for Dye-Sensitized Solar Cells

Miao-Syuan Fan<sup>1</sup>, Chuan-Pei Lee<sup>1</sup>, Chun-Ting Li<sup>1</sup>, Yi-June Huang<sup>1</sup>, R. Vittal<sup>1</sup>, and Kuo-Chuan Ho<sup>1,2\*</sup>

<sup>1</sup> Department of Chemical Engineering, National Taiwan University, Taipei 10617, Taiwan

\* E-mail: kcho@ntu.edu.tw

Recently, molybdenum disulfide ( $\text{MoS}_2$ ) and graphene (Gr) have been considered as attractive 2-dimensional (2D) materials due to their good catalytic activity and conductivity, and they have many potential applications in electronic devices, including lithium storage, photoresponsive memory devices and dye-sensitized solar cells (DSSCs). Compared with pristine Gr, the nitrogen-doped graphene (NGr) could compensate the deficiency of active sites without decrease the conductivity, which enhanced the performance of electrochemical reaction. On the other hand, molybdenum sulfide ( $\text{MoS}_2$ ) with its remarkable properties such as catalytic ability and mechanical strength, which can be used over a wide electrochemical system and electronic device. However, the weak point of  $\text{MoS}_2$  is that the active site is limiting to its edge. Thus, the approach to expose the edge of  $\text{MoS}_2$  is a critical segment to improve the performance of this material.

In this study, we prepared various NGr/ $\text{MoS}_2$  composite films via simple drop-coating method as the counter electrode (CE) for DSSCs. As shown in Fig. 1, when the  $\text{MoS}_2$  sheet was used as the CE in a DSSC, it showed a low cell efficiency ( $\eta$ ) of 6.20% ( $V_{OC}$  of 0.79 V,  $J_{SC}$  of  $13.46 \text{ mA cm}^{-2}$ , and  $FF$  of 0.58), while that of the cell showed an  $\eta$  of 6.20% ( $V_{OC}$  of 0.68 V,  $J_{SC}$  of  $12.72 \text{ mA cm}^{-2}$ , and  $FF$  of 0.64) when the bare NGr was used as a CE. We fabricate various NGr/ $\text{MoS}_2$  composite CEs by varying the weight ratio of NGr from 0 to 12wt%. The optimized  $\eta$  of 7.82% ( $V_{OC}$  of 0.77 V;  $J_{SC}$  of  $15.36 \text{ mA cm}^{-2}$ , and  $FF$  of 0.66) was achieved for the DSSC with an NGr/ $\text{MoS}_2$  composite film (8wt% NGr), which is comparable to that of the cell with a platinum (Pt) CE (8.25%). Due to the presence of NGr support, the  $\text{MoS}_2$  exposes more edges for the electrochemical reduction of  $\text{I}^-/\text{I}_3^-$  (Fig. 2). The cyclic voltammetry (CV), electrochemical impedance spectra (EIS), and Tafel curve show that the NGr/ $\text{MoS}_2$  composite film exhibits the superior electrocatalytic ability for the reduction of  $\text{I}_3^-/\text{I}^-$ . Moreover, the rotating disc electrode (RDE) was used to calculate the effective electrocatalytic surface area ( $A_e$ ) of NGr/ $\text{MoS}_2$  composite film ( $0.73 \text{ cm}^2$ ), which is much larger than that of Pt ( $0.196 \text{ cm}^2$ ). The analysis confirmed that the NGr/ $\text{MoS}_2$  composite CE is a noteworthy Pt substitution for the CE in DSSCs.

Fig. 1 Photocurrent density–voltage curves of the DSSCs with  $\text{MoS}_2$ , bare NGr, Pt, and NGr/ $\text{MoS}_2$  (8wt% NGr) CEs, obtained at  $100 \text{ mW cm}^{-2}$ .

Fig. 2 SEM for the NGr/ $\text{MoS}_2$  composite film (8wt% NGr).

# A Pt-Free Counter Electrode based on Novel Cobalt Diselenide Architectures for Dye-Sensitized Solar Cells

Platinum (Pt) is one of the preferred electrocatalytic materials for electrochemical devices, including fuels cells, water electrolyzers, and dye-sensitized solar cell (DSSCs). However, the overuse of Pt limits its future usage. Therefore tremendous efforts have focused on the development of Pt-free counter electrode (CE) for DSSCs. Recently earth-abundant inorganic electrocatalysts have been widely investigated as promising CE materials for DSSCs. Here we report the synthesis of novel cobalt diselenide (CoSe<sub>2</sub>) architecture for use as the CE in DSSCs.

In this study, we synthesize CoSe<sub>2</sub> crystals with structures of atomic shell (Fig. 1a) by surfactant-assisted hydrothermal technique using the nonionic surfactant Triton<sup>®</sup> X-100. From the X-ray diffraction (XRD) analysis, the synthesized CoSe<sub>2</sub> crystals show obvious peaks corresponding to (200), (210), (211), (220), (311), (023), (311), (023) planes of CoSe<sub>2</sub> (JCPDS card no. 89-2002). As shown in Fig. 1b, the scanning electron microscopy (SEM) images reveal that the atomic shell-like CoSe<sub>2</sub> crystal has extremely rough surface for each shell, and it has an outer diameter of 40  $\mu\text{m}$  and a shell thickness of 250 nm. We inferred from the SEM images that the rough and two-sided surfaces of each shell of the atomic shell-like CoSe<sub>2</sub> crystal would be meritorious in the present work as high surface area is effective for the reduction reaction of triiodide (I<sub>3</sub><sup>-</sup>). Subsequently, the atomic shell-like CoSe<sub>2</sub> crystals was coated on fluorine-doped tin oxide (FTO) substrate as the CE for a DSSC, which was consisted of a TiO<sub>2</sub> film adsorbed with N719 dye as the photoanode. A power conversion efficiency ( $\eta$ ) of 6.08% with an open-circuit voltage ( $V_{\text{OC}}$ ) of 0.70 V, a fill factor ( $FF$ ) of 0.62, and a short-circuit current density ( $J_{\text{SC}}$ ) of 14.06  $\text{mA cm}^{-2}$  was achieved under the illumination of simulated solar light (AM 1.5G) with intensity of 100  $\text{mW cm}^{-2}$ , which is significantly higher than that of a cell using a CE with the commercial CoSe<sub>2</sub> crystals ( $\eta$ : 4.27%,  $V_{\text{OC}}$ : 0.71 V,  $FF$ : 0.61,  $J_{\text{SC}}$ : 9.91  $\text{mA cm}^{-2}$ ).

Fig. 1 (a) Schematic representation of atomic shell structure. (b) The SEM image of the atomic shell-like CoSe<sub>2</sub> crystal.

Fig. 2 Photocurrent density-voltage curves of the DSSCs with the commercial CoSe<sub>2</sub> crystals and the atomic shell-like CoSe<sub>2</sub> crystals on their CEs, measured under 100  $\text{mW cm}^{-2}$  (AM 1.5G).

# Synergistic Electrocatalytic Effects on Oxides + Ag - Electrodes for Oxygen Reduction and Evolution

Hatem M. A. Amin, Lingxing Zan, Mohammed Soltani, Sevda Ayata, Christoph Bondü, Helmut Baltruschat  
*University of Bonn*  
*Roemerstrasse 164, 53117 Bonn*  
*baltruschat@uni-bonn.de*

For metal air batteries, a highly reversible electrocatalyst is needed, i. e. a catalyst for both OER and ORR. In alkaline solution, Ag is known to be the best electrocatalyst for oxygen reduction. However, Ag is not catalyzing oxygen evolution. Spinel oxides such as  $\text{Co}_3\text{O}_4$  and various Perovskites have been shown to be good catalysts for oxygen evolution but are not very good for oxygen reduction. We have recently shown that a particular mixture of a Ag catalyst with  $\text{Co}_3\text{O}_4$  nanoparticles leads to a catalyst which not only combines the good performance of Ag for the ORR with that of  $\text{Co}_3\text{O}_4$  for the OER, but shows a better activity than its components.<sup>1, 2</sup>

Here, we will present further insights and demonstrate that this effect is also observed for various perovskites. The effect is also observed when  $\text{Co}_3\text{O}_4$  or the perovskites are deposited on smooth Ag electrodes. We determined the free Ag surface area by underpotential deposition of Pb and thus showed that the specific synergistic effect per free Ag surface area is even larger.

Using differential electrochemical mass spectrometry (DEMS) and  $^{18}\text{O}$  - isotope exchange has been shown in the past that during oxygen evolution at oxides the oxygen of the lattice is participating in the oxygen evolution reaction.<sup>3-6</sup> This method will be applied to the above catalysts as well.

## A Shortcut: Core (Rutile) – Shell (Anatase) Nanorods for Highly Efficient Solar Water-Splitter

Hogiartha Sutiono, Ching-Hsiang Chen, Wei-Nien Su, Liang-Yih Chen\*, Bing-Joe Hwang\*  
*Department of Chemical Engineering, National Taiwan University of Science and Technology*  
43, Section 4, Keelung Road, Taipei 106, Taiwan  
[sampras@mail.ntust.edu.tw](mailto:sampras@mail.ntust.edu.tw) (Liang-Yih Chen) & [bjh@mail.ntust.edu.tw](mailto:bjh@mail.ntust.edu.tw) (Bing-Joe Hwang)

In this study, the crystal growth behavior of TiO<sub>2</sub> nanorods (NRs) array, which was directly grown on the FTO substrate, could be controlled through a simple procedure. It was found that the position of FTO substrate inside the Teflon-liner during hydrothermal synthesis was strikingly important to control the preferred crystal growth direction. By simply changing the position of FTO substrate, TiO<sub>2</sub> NRs array with unusual crystallographic properties could be obtained. Interestingly, it could produce a remarkable saturation photocurrent of 2.32 mA cm<sup>-2</sup> at 1.23 V<sub>RHE</sub> which outclassed any published reports for pristine TiO<sub>2</sub> photoanode water-splitter. Initially, the finding of unusual crystallographic properties ((110) and (101) facets) was believed severely enhanced the photoelectrochemical (PEC) water-splitting performance. But, after the anatase phase was found in the NRs system, the exact role of (110) and (101) facets towards this superior PEC water-splitting performance became obscured. The existence of anatase phase, which was revealed by Raman spectroscopy technique, was considered to be the main factor in improving charge separation and PEC water-splitting performance simultaneously. The strategy of adding saturated aqueous solution of a particular salt additive into the crystal growth solution not only could modulate the interaction between NRs, but also could control the portion of anatase phase in the NRs system. It was understandable that the wider distance between NRs could enlarge the accessible surface area of the NRs which could facilitate a better charge transfer in the electrode/electrolyte interface. Regarding the arrangement between rutile and anatase phases in the NRs, it was predicted that the anatase phase was naturally formed on the surface of NRs (anatase phase acted as the shell part). This prediction got confirmed by the Transmission Electron Microscopy (TEM) and Tip Enhanced Raman Spectroscopy (TERS) results which were taken from the edge of the nanorod. In addition, annealing temperature variation was selected to investigate the phase transformation and its effect on PEC water-splitting performance. Lastly, it is noteworthy that the existence of anatase phase was not the only factor that could enhance the PEC water-splitting performance. The unusual crystallographic properties of the rutile core part as the result of FTO substrate position modification during hydrothermal synthesis, was believed also responsible in this superior performance.

# The effect of surface functional groups of carbon nanofiber on oxygen reduction reaction

In our previous studies, we have studied the effect of CNFs surface microstructures and functional groups on oxygen reduction reaction (ORR) by using CNFs as catalyst or catalyst support to load metal nanoparticles. The P-CNFs exhibit the highest ORR activity because they have higher ratio of edge atoms to basal atoms, and the T-CNFs have the most negative ORR onset potential and the least ORR peak current for their lowest ratio of edge atoms to basal atoms<sup>[1-2]</sup>. By using CNFs as support, the electrocatalyst supported on P-CNFs shows higher electrochemical surface area and more positive ORR onset reduction potential than electrocatalyst supported on other CNFs and activated carbon<sup>[3-4]</sup>.

Surface functional groups are showed to have a positive influence on the ORR activity of CNFs. As shown in Table 1, CNFs with nitrogen-containing groups exhibit the highest ORR activity, followed by carboxyl groups, carbonyl groups and hydroxyl groups. The oxygen reduction of CNFs with nitrogen-containing groups proceed almost entirely through the four-electron reduction pathway, while the electrodes of CNFs with carboxyl groups, carbonyl groups and hydroxyl groups proceed a two-electron reduction at low potentials followed by a gradually four-electron reduction at more negative potentials.

We also have found CNFs with hydroxyl groups (CNF-OH) are more conducive to support Pt catalyst than carboxyl groups (CNF-OX), so Pt/CNF-OH presents a better activity towards ORR than Pt/CNF-OX.

Table 1 Electrochemical data for five modified CNF/GC electrodes.

Sample	$E_{OP}$ (V)	$E_p$ (V)	$j_p$ ( $\text{mA}\cdot\text{cm}^{-2}$ )	$n$ @0.6V K-L plot
CNF-P	-0.222	-0.344	-0.339	2.11
CNF-OX	-0.144	-0.254	-0.384	2.43
CNF-OH	-0.166	-0.281	-0.350	2.19
CNF-CO	-0.144	-0.264	-0.363	2.35
CNF-ON	-0.134	-0.286	-0.788	3.25

Fuel cells have been considered as potential candidate for alternative energy generation system. Unfortunately, the use of precious Pt catalyst limits its wide spread application. In order to reduce the cost, the research focus was suggested to shift from proton exchange membrane fuel cell to alkaline anion exchange membrane system. The hydrogen oxidation reaction (HOR) on anode side is fast in acidic environment, whereas in alkaline environment the reaction rate is two ordered magnitude lower than that in acidic. Therefore, enhancement of reaction kinetic for HOR in alkaline media is the key for improving the performance of entire fuel cell system.

In this study, the non Pt-based catalyst was developed for applied in hydrogen oxidation reaction. The non-precious Ni-based catalyst, alloying with Pd and Ru as the second metals, has been developed. In the catalyst preparation, the modified watanabe method has been adapted to prepare bimetallic NiM(M=Pd, Ru) catalyst. The synthesized bimetallic catalysts is well alloyed and the size in between 3-5 nm. The hydrogen oxidation activity was evaluated by cyclic voltammograms (CV) and linear sweep voltammograms (LSV) on the rotating disk electrode in 0.1 M KOH alkaline media. The catalysts exhibit comparable catalytic activity for HOR as compared to commercial Pt/C catalyst. In addition, the synthesized bimetallic catalyst shows superior activity than Pt/C towards hydrogen evolution reaction. The developed bimetallic NiM(M=Pd, Ru) catalyst is promising candidate to replacing Pt as HOR catalyst and has potential to be bifunctional catalyst for catalyzing both hydrogen oxidation and evolution reaction.

# **Physioelectrochemical properties and catalytic activity of green synthesized metal oxide nanoparticles and conductive polymer composite film**

NiO nanostructures (NiONPs ) have been extensively investigated because of their promising applications in various fields. NiO nanostructures are potential catalysts for oxidation reactions of CO and for substituting noble metal catalysts due to their high catalytic activity, low-cost, and availability. Ni-based and its oxide-based nanomaterials were of great interest for their extensive applications in catalysis, gas sensor, Li ion battery and biosensors for a long time. The study of conducting polymer modified electrodes is motivated primarily from the anticipation of a synergistic electrocatalytic benefit from the very good conducting and mechanical properties and their good adhesion to the electrode substrate [1, 2]. Herein, we describe a simple strategy dispersing of NiONPs within the conducting polymer matrix by in situ electropolymerization using an ionic surfactant as the supporting electrolyte.

In this work, NiONPs was prepared by a simple and green method using Rosmarinus officinalis extract containing phenolic constituents as both the chelating and the stabilizing agents. NiO nanoparticles/poly ortho amino phenol composite as electro-active electrodes for electro catalytic oxidation of methanol with good uniformity are prepared by electropolymerization. Composite of NiONps/POAP was synthesized by cyclic voltammetry (CV) methods and electrochemical properties of film were investigated by using electrochemical techniques. New composite modified electrode shows a significantly higher response for methanol oxidation.

# Orange II mineralization on C-modified nanoparticulate TiO<sub>2</sub> cathodes able for producing OH<sup>•</sup> radicals through the O<sub>2</sub> reduction which is simultaneously generated on a grade 2 Ti anode via the H<sub>2</sub>O oxidation

In this investigation we study the orange II dye mineralization on C-modified nanoparticulate TiO<sub>2</sub> cathodes (**OTE/npTiO<sub>2</sub>/C**, where an optically transparent electrode (OTE) and carbon vulcan powder (C) were utilized as conductive substrate and carbon material, respectively) that can produce OH<sup>•</sup> radicals through the O<sub>2</sub> reduction. In this way, the O<sub>2</sub> consumed by the **OTE/npTiO<sub>2</sub>/C** cathodes is simultaneously produced on a grade 2 Ti anode where the H<sub>2</sub>O oxidation is carried out. On the other hand, the orange II mineralization was also carried out on bare nanoparticulate TiO<sub>2</sub> electrodes (**OTE/npTiO<sub>2</sub>**) for comparison purposes.

Our results showed a color removal of 99% (estimated by absorbance reduction at 480nm) when a potential of -0.1V vs. Ag|AgCl (3M NaCl) is applied to the system **OTE/npTiO<sub>2</sub>/C** which remains immersed for 7 h in an O<sub>2</sub>-saturated electrolyte. This electrolyte condition was achieved with the aid of the Ti counter-electrode that simultaneously oxidizes H<sub>2</sub>O at a potential of +1.4V vs. Ag|AgCl (3M NaCl), which is promoted after the anode polarization is activated. On the contrary, the color removal efficiency for the system **OTE/npTiO<sub>2</sub>** achieves only 16% for the same experimental setup, thus revealing that the O<sub>2</sub> reduction on the **OTE/npTiO<sub>2</sub>/C** electrodes was enhanced by the presence of the C materials. Complementarily, the remnant total organic carbon (TOC) that were measured for the electrochemical treatments carried out with **OTE/npTiO<sub>2</sub>/C** and **OTE/npTiO<sub>2</sub>** electrodes showed values of 55 and 85%, respectively, in good accordance with the color removal tendencies.

To better understand the last results, the production of OH<sup>•</sup> radicals on **OTE/npTiO<sub>2</sub>/C** and **OTE/npTiO<sub>2</sub>** electrodes was followed during the first 1 h of the electrochemical treatments. Interestingly, it was found that the OH<sup>•</sup> generation from both TiO<sub>2</sub> surfaces has the same tendency in the absence or in the presence of C materials, thus indicating that the OH<sup>•</sup> radicals generation do not depend from the applied potential to the anodes because these species should be chemically produced after the O<sub>2</sub> reduction is taking place. On the contrary, the measured charge transfer resistances ( $R_{ct}$ ) for the O<sub>2</sub> reduction on polarized **OTE/npTiO<sub>2</sub>/C** (10.17k $\Omega$ ) and **OTE/npTiO<sub>2</sub>** (45.47k $\Omega$ ) electrodes clearly revealed that the O<sub>2</sub> reduction rate on the **OTE/npTiO<sub>2</sub>/C** electrodes was 4.5 times faster than for the **OTE/npTiO<sub>2</sub>** electrodes. This result strongly suggest that the color removal on **OTE/npTiO<sub>2</sub>/C** electrodes it was predominantly promoted by the products of the O<sub>2</sub> reduction (O<sub>2</sub><sup>•-</sup>, HO<sub>2</sub><sup>•-</sup>), which are thermodynamically able for activate the reduction of the azo groups (N=N) localized in the molecules of orange II. Finally, the mineralization process of the previously reduced orange II molecules was enhanced with the aid of the chemically generated OH<sup>•</sup> radicals.

# Study of ethanol electro-oxidation on PtNd/C and PtSnNd/C: stability test and FTIR.

Nathalia Abe Santos\*, Patricia Gon Corradini and Joelma Perez  
Instituto de Química de São Carlos, Universidade de São Paulo (USP),  
Avenida Trabalhador São-carlense 400, 13560-970, São Carlos, Brazil  
\*abe.nathalia@yahoo.com.br

The development of efficient catalysts for direct ethanol fuel cells (DEFC) requires to understand the influence of physical and chemical properties of materials in catalytic activity. Therefore, this abstract describes the preparation of carbon-supported catalysts with a metal load of 20% wt, (metal = Pt, Sn and/or Nd) by formic acid method<sup>1</sup> and the study of their catalytic activities for ethanol oxidation reaction. The catalysts were characterized by physical and electrochemistry techniques. X-ray diffraction analysis showed diffraction patterns with typical peaks of face-centered cubic structure of Pt. Average particle sizes of 4 and 5 nm were respectively observed for PtSn/C and Nd-based catalysts by transmission electron microscopy. EDX data indicated the catalysts composition: PtSn (90:10), PtNd (76:24) e PtSnNd (71:12:17). XPS analysis was performed for all catalysts. The catalytic activity for ethanol oxidation was evaluated for potential sweeps and chronoamperometry. Performing analysis at activity for ethanol oxidation after and before stability evidenced that Nd-based catalysts (PtNd/C and PtSnNd/C) have the largest activity for ethanol oxidation reaction after test. CO stripping measurements also showed a significant change in the form of linear sweep voltammetry curves of CO oxidation after and before stability for catalysts PtSn/C and PtSnNd/C. This change was not observed for PtNd/C catalyst. It is known that CO electro-oxidation reaction on Pt is structure-sensitive<sup>2</sup>, the results can indicate changes in the surface structure of Sn-based catalysts, whereas no changes are observed on surface structure of PtNd/C. The evaluation of products and intermediaries of the ethanol oxidation reaction by Fourier transform infrared spectroscopy indicated the formation acetaldehyde and acetic as the main products and CO<sub>2</sub> traces. In conclusion, these findings clearly demonstrate that, despite the low reaction yielding, all catalysts are able to break C-C bonds and generated CO<sub>2</sub>. In addition, compared to PtSn/C catalyst, Nd-based catalysts present enhanced catalytic activity for ethanol oxidation after stability test and such improvement can be influenced by the presence Nd on the surface structure of catalyst.

CO<sub>2</sub> is one of the most widely known greenhouse gases which cause the global warming, therefore CO<sub>2</sub> capture and sequestration have attracted much attention. Water gas shift (WGS) is a reaction for producing CO<sub>2</sub> and H<sub>2</sub> from CO and water vapor. Conversely, it is possible to remove CO<sub>2</sub> from the air via reverse water gas shift (RWGS) reaction which is an endothermic reaction above 600°C.[1-2] Also, coupling the RWGS reaction with the co-electrolysis can produce synthesis gas (i.e. syngas) consisting of H<sub>2</sub> and CO, a Fischer-Tropsch (FT) process converts the syngas into hydrocarbons which is useful fuels such as gasoline, diesel, ethanol and methanol. However, catalyst materials for RWGS reaction are limited to noble metals such as Pt, Rh, Pd and Au, because RWGS reaction requires high operating temperature. Although the noble metals show highly catalytic activity and stability at elevated temperature, they have significant barriers to commercialization due to high cost and limited natural abundance. Therefore, it is necessary to develop cost-effective and highly active catalyst for low-temperature RWGS reaction. In this study, composite catalyst, which includes iron oxide as catalyst and gadolinia-doped ceria (GDC) as oxygen storage, was fabricated for the reduction of CO<sub>2</sub> in RWGS reaction. Catalytic tests were carried out in a fixed-bed quartz reactor with a different gas mixture ratio of CO<sub>2</sub> and H<sub>2</sub> as reactants in the temperature range of 450 to 700°C. The gases which passed through the composite catalyst were injected to gas chromatograph (GC), and then the CO<sub>2</sub> conversion rate and CO selectivity were analyzed. From the experimental results, it was confirmed that the obtained composite catalyst for the reduction of CO<sub>2</sub> shows highly catalytic activity corresponding noble metals such as Pt, Rh, Pd and Au.

Sulfur containing compounds as the methyl-substituted dibenzothiophene, are very recalcitrant substances and are associated with environmental problems in soils, water and atmosphere. In this work the model molecules dibenzothiophene (DBT) and dibenzothiophene sulfone (DBTO<sub>2</sub>) were electrochemically degraded in an acetonitrile-aqueous system on platinum electrodes at 32 mA cm<sup>-2</sup>. As result of the oxidation-reduction process of 920 ppm of DBT or DBTO<sub>2</sub> in a not divided cell, two liquid immiscible phases were formed: a) a high dense phase (HDP), and b) a lower density phase (LDP). These two phases were separated and analyzed by GC-FID, GC-MS, HPLC-DAD, UV-Vis and FTIR techniques. The LDP analysis of the electrolyzed solution of DBT by GC-FID using a polar column showed that the DBT was completely degraded (Fig. 1a and b) and only one product was detected. In the HDP a greater number of products (\*) were detected (Fig.1c). These compounds are substantially more polar than those that remain in the LDP. The last was demonstrated by the values of the conductivity, pH and by chromatography. GC-MS analysis using a non-polar column of the LDP after electrolysis showed that the products P1 and P2 are the same for DBT and DBTO<sub>2</sub> (Fig. 2a and 2b). The analysis of the electrolysis products and the percentage of DBTO<sub>2</sub> removed from the reaction mixture ACN-H<sub>2</sub>O during 6 hours of electrolysis was studied by HPLC-DAD (Fig. 3).

# Electrochemical Investigation of Water Reduction on Goethite, Lepidocrocite and Mild Steel in Slightly Alkaline Electrolyte

Kristoffer Hedenstedt<sup>1,2</sup>, Nina Simic<sup>1</sup>, Mats Wildlock<sup>1</sup> and Elisabet Ahlberg<sup>2</sup>

<sup>1</sup>AkzoNobel Pulp and Performance Chemicals, SE-445 80 Bohus, Sweden

<sup>2</sup>Department of Chemistry and Molecular Biology, University of Gothenburg,

Kemigården 4, SE-412 96 Gothenburg, Sweden

kristoffer.hedenstedt@chem.gu.se

Cathodes made out of mild steel were taken from two different sodium chlorate plants presenting completely different characteristics. Surface characterisation with SEM, EDX and XRD showed that goethite was present on one of them while lepidocrocite was the corrosion product present on the second. It was also established that the electrode with lepidocrocite had longer starting period, i.e. before reaching sufficient current efficiency.

The kinetics of the hydrogen evolution reaction was studied on the two different iron-oxy-hydroxides as well as on fresh mild steel under slightly alkaline conditions. Tafel slopes of 200-250 mV/decade showed that the first electron transfer is rate limiting but the transfer coefficient is small, ranging from 0.24 to 0.3, Figure 1. It is concluded that the hydrogen evolution reaction on all three electrodes takes place on  $\text{Fe}(\text{OH})_2$ , which must first be formed on the surface [1, 2]. Since the transfer coefficient is low, the transition state is closer to the adsorbed hydrogen than to the water in solution. Hence the active site for water reduction is proposed to be the protonated  $\equiv \text{Fe}(\text{II})-\text{OH}_2^+$  surface group independent if the starting material is  $\alpha$ -FeOOH,  $\gamma$ -FeOOH or mild steel. The mechanism for hydrogen evolution is discussed in the

context of the general Volmer-Tafel-Heyrovsky scheme valid for metal surfaces. The kinetic results indicate that the thickness and conductivity of the layers are more important for the performance than the crystallographic structure of the oxide

The large development of the polymer electrolyte membrane fuel cells in the last decades has made the oxygen reduction a widely investigated reaction. Due to its sluggish kinetics, extensive research is devoted to find optimal electrocatalysts for the oxygen reduction reaction (ORR). As a consequence, the study of the ORR has become one of the standard electrochemical analyses for the characterization of electrocatalysts.

The catalytic activity towards the ORR can be studied by linear sweep voltammetry in combination with a rotating disc electrode (LSV/RDE) [1]. Besides the kinetic characterization, the technique allows identifying the reaction mechanism with the quantification of the number of electrons transferred. The kinetic study of the electrocatalysts often involves the use of the Koutecky-Levich analysis to calculate the number of transferred electrons and the kinetic current. At the diffusion limited current region, the number of electrons is estimated; whereas the catalytic activity (i.e. the kinetic current) is estimated at low overpotentials for the ORR, where the fuel cell would perform. Therefore, the determination of the characteristic electrochemical parameters of the catalyst is obtained by means of the analysis at two potentials of separated regions of the current-potential experiment. This is done at the risk of neglecting irregularities on the current-potential response of the material, which might be present at the selected potentials, altering the shape of the LSV/RDE curve and making the Koutecky-Levich analysis difficult.

In this work, the electrochemical parameters of catalysts are determined from LSV/RDE experiments by means of a statistically-founded fitting procedure [2-3]. This method offers the advantage of using one integrated current-potential relation that accounts for mass and charge transfer steps. Hence, the whole polarization curve is considered, rather than just the part in which only mass or charge transfer is supposed to be rate determining. In this sense, it brings an enormous advantage to the analysis of electrocatalytic processes. The procedure is designed for the reliable determination of characteristic parameters (i.e. number of electrons, kinetic current and charge transfer coefficient) from only one LSV/RDE experiment. Provided that the experimental reproducibility is ensured, this methodology eliminates the need of multiple experiments to characterize quantitatively the electrochemical system. This aspect is also a benefit for assessing the catalytic activity, reducing the problematic related to the ageing of the electrocatalyst. Recently, this method has been proven to represent a strong tool to detect deviations of actual LSV/RDE measurements from the theoretical curve [3], which is of great interest to understand the mechanism of the electrochemical process.

Nanostructured Pt catalysts are chosen for this study due to their high activity towards the ORR and high surface to volume ratios. Pt dendritic nanostructures are electrodeposited on glassy carbon RDEs by a potentiostatic double pulse, optimized to enhance the electrochemically active surface area [4-5]. To characterize the catalysts electrochemically, LSV/RDE experiments with different rotation speeds are performed. The experimental data are used to investigate the interesting advantages of the fitting methodology for the reliable estimation of the characteristic parameters of the electrocatalytic process.

# Synthesis of MnO<sub>2</sub>/Carbon Composites as Electrode Materials for Supercapacitors

Chien-Te Hsieh, Dong-Ying Tzou, Hsiu-Hui Hsu, Yu-Ming Chiang  
Department of Chemical Engineering and Materials Science, Yuan Ze University  
135 Yuan-Tung Road, Chung-Li 32003, Taiwan  
[cthsieh@saturn.yzu.edu.tw](mailto:cthsieh@saturn.yzu.edu.tw)

## Abstract

Carbon nanotubes (CNTs) and graphene nanosheets (GNs) supported by MnO<sub>2</sub> nanoneedles have been synthesized through a chemical-wet route without any thermal treatment. The electrochemical capacitive performances of MnO<sub>2</sub>/carbon composite electrodes are characterized by cyclic voltammetry, galvanostatic charge-discharge cycling, and *ac* impedance spectroscopy.

The electrochemical performance of MnO<sub>2</sub>-based capacitors is enhanced by the synergistic effect that combines the MnO<sub>2</sub> and the carbon supports, promoting more active sites available for charge transfer and electric double-layer in the hybrid architecture. The enhanced performance of MnO<sub>2</sub>-based capacitors can be ascribed to the fact that the design of hybrid structure is capable of (i) maximizing the utilization of MnO<sub>2</sub> nanoneedles and (ii) leading to fast chemical reaction kinetics including ionic electro-sorption and charge transfer. This method provides a simple and fast way to deposit MnO<sub>2</sub> onto carbon supports as electrode materials for energy-storage devices.

**Keyword:** Electrochemical capacitors; Manganese dioxide; Graphene nanosheets; Carbon nanotubes; Specific capacitance

Figure 1. Schematic illustrating (a) the morphologies of MnO<sub>2</sub>, CNT-M, and GN-M composites through the chemical-wet way, and (b) the diffusion of Li ions through different MnO<sub>2</sub> nanostructures from Li<sub>2</sub>SO<sub>4</sub> electrolyte.

# New palladium phosphide catalysts for fuel cell relevant reactions

A. Kucernak, K. F. Fahy, B. Kakati, V. N. Naranammalpuram Sundaram

Department of Chemistry, Imperial College London  
South Kensington, London SW7 2AZ, United Kingdom  
anthony@imperial.ac.uk

A number of recent publications have demonstrated the interesting corrosion and catalytic properties of transition metal phosphides in acidic media[1-3]. These phosphides may have interesting applications as durable electrocatalysts in polymer electrolyte membrane fuel cells (PEMFCs) direct methanol fuel cells (DMFCs), and electrolyzers.

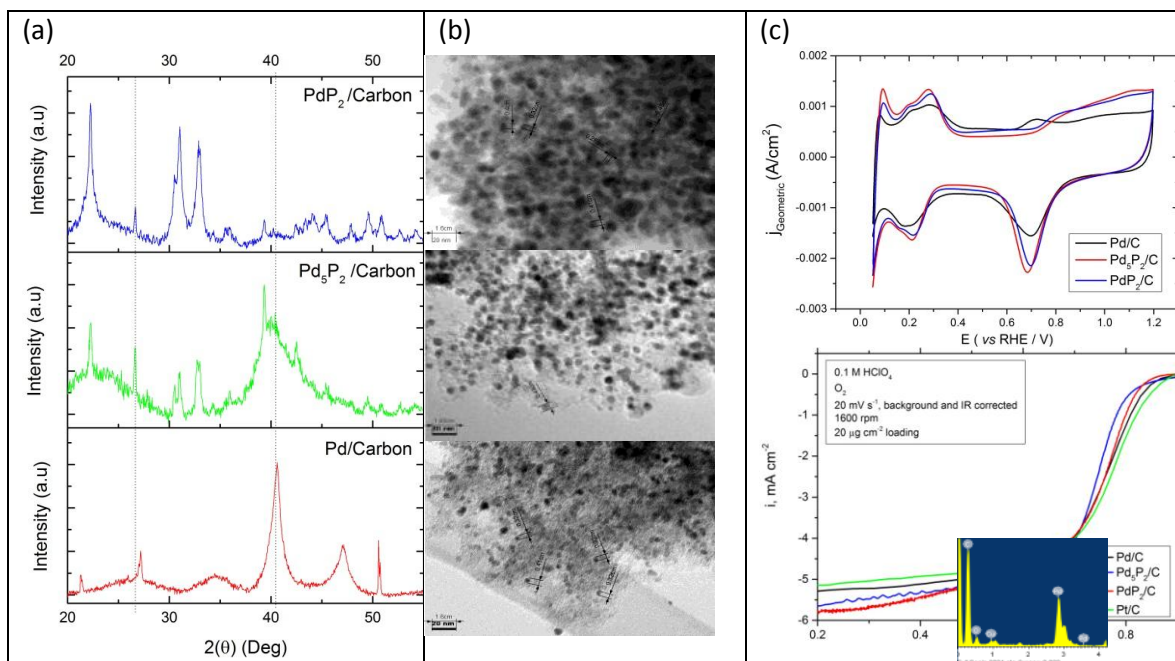

Although Palladium is often touted as a potential alternative to platinum as an electrocatalyst, it suffers from lower stability, due to the higher solubility and lower thermodynamic stability of palladium in acidic media. One method of improving stability is by alloying the palladium with phosphorus, which is known in the literature to produce corrosion resistant compounds[4], which can be important in achieving good electrochemical stability[3].

In this study we demonstrate an easily scalable method for producing carbon-supported transition metal phosphides and use this method to produce palladium phosphides containing 28 at.% and 33 at.% phosphorus. XRD and TEM demonstrated that the palladium phosphides showed the same particle size (~5 nm) and morphology as the Pd/C precursor, making them easy to incorporate into a fuel cell, without the need for an additional support.

The palladium phosphides show increased activity towards the HOR compared to the Pd/C and also promising HER activity in 0.1 M perchloric acid. The ORR activity of the phosphides was also promising, with good stability of potential cycling compared to Pd/C and Pt/C.

Thermogravimetric analysis shows that the phosphides also have increased stability compared to Pd/C and the electrochemical durability of the phosphides is also good compared to the Pd/C.

The catalysts were tested as both anode and cathode catalysts in a polymer electrolyte fuel cell.

**Figure 1** (a) XRD traces of the Pd/C precursor and the palladium phosphide materials. (b) TEM images of the Pd/C and palladium phosphide materials. (c) CV and HER activity of the Pd/C and palladium phosphides performed in 0.1 M perchloric acid.

Hydrogen fuel cell driven electric vehicles represent a promising technology on the verge of market introduction, but the efficiency of fuel cells is still far below the thermodynamic limit. The high amount of Pt catalyst therefore required to deliver the power needed leads to costs too high for widespread market introduction, especially in the automotive sector. Especially overpotentials of several hundred mV at the cathode side due to the sluggish kinetics of the oxygen reduction reaction (ORR) is responsible for these drawbacks.

Catalytic materials with higher activity for the ORR and enhanced durability as well as reduced Pt loading can both bring down the costs and enhance the efficiency and therefore the competitiveness of fuel cell driven vehicles. Recently it has been shown that polycrystalline Platinum - rare-earth metal (RE) alloys show very promising catalytic properties for ORR, e.g. an increase in the kinetic current density by a factor of 3-5 compared to pure Pt [1,2]. They were reported to show a good stability due to their high heat of formation and the formation of a dense Pt overlayer during the initial de-alloying steps [2]. The overlayer is under compressive strain, causing the high activity [2]. Also for Pt-RE nanoparticles prepared in a cluster source, an enhanced mass activity was found [3].

For applying these alloys in actual fuel cells, the major challenge is to synthesize such nanoparticles with a method, which can be up-scaled to provide enough material for MEA fabrication and subsequently for widespread production for practical applications. This is challenging due to the very low standard potentials of the rare earth elements.

In this study electrochemical deposition was selected as a scalable method. However, due to the low deposition potential of rare-earth metals, aqueous electrolytes could not be used for these experiments. Therefore ionic liquids were chosen as electrolyte, because they offer a wide electrochemical window and in literature a successful deposition of selected pure rare-earth metals had been claimed [4], but there are also reports showing fundamental obstacles for deposition of RE metals from some ionic liquids [5]. Therefore in a second approach organic solvents with an added supporting electrolyte were evaluated, which have also a wide potential window and where high amounts of precursors can be dissolved.

For both electrolyte systems, the electrochemical processes in solutions containing Pt precursors, rare earth metal ions and mixtures of both for alloy deposition were discussed by the use of electrochemical techniques, partially in combination with the electrochemical quartz crystal microbalance (EQCM) technique, and ex-situ and in-situ scanning probe microscopy techniques as well as electrocatalytic measurements for the ORR. Aside from the gold electrode of the EQCM, Boron-doped Diamond (BDD) was used as working electrode, as it is a very inert electrode and allows even wider potential windows in non-aqueous media [6]. Deposited layers were characterized by EDS and surface science methods.

# **Ru/M Bi-layered Oxide Catalysts for Oxygen Evolution Reaction (OER) in Acidic Water Splitting**

Jin Yeong Kim, Jihui Choi, Sung Hoon Hong, Hoyoung Kim, Eunkyong Hwang and Soo-Kil Kim  
*School of Integrative Engineering, Chung-Ang University,  
Heukseokno 84, Dongjak-gu, Seoul 156-756, Republic of Korea  
sookilkim@cau.ac.kr*

Due to the sluggishness of the oxygen evolution reaction (OER) and its harsh conditions of low pH and high overpotential, development of a highly active and stable catalysts<sup>(1,2)</sup> have been a long huddle for the commercialization of acidic water electrolysis. Besides the well-known Pt-based catalysts, PGM oxides such as RuO<sub>x</sub> and IrO<sub>x</sub> have been largely investigated<sup>(4,5,6)</sup>, still the necessity to lower the cost and enhance their activity and stability remains.

In this work, Ru/M (M=transition metal) bi-layered catalysts were fabricated using electrodeposition on Ti substrates. The oxides were further fabricated by annealing process in air condition at various temperatures. OER activity and stability of the various Ru/M bi-layered oxides were investigated by cyclic voltammetry. The enhanced catalytic properties were correlated with the material characteristics investigated through various characterization tools including FESEM, XPS, EDS, XRD, etc.

The results indicated that surface morphologies, roughness, and modification of electronic structure evolved by M as well as the annealing conditions were responsible for the enhanced catalytic properties of Ru/M bi-layered oxide catalysts over conventional thermal RuO<sub>x</sub> catalysts.

Electrochemical reduction of CO<sub>2</sub> to C1 fuel has recently been intensively studied as a method to reduce and utilize CO<sub>2</sub>. Under proper reduction conditions including types of catalysts, electrolytes, and reduction potential, CO<sub>2</sub> can be converted into various types of useful fuels such as formic acid, carbon monoxide, methane, and longer hydrocarbons [1, 2, 3].

Among the converted fuels, formic acid is highly desired due to its various applications as a feedstock chemical and the fuel of direct formic acid fuel cell. Some transition metal catalysts such as Hg, Pb, Cd and Tl have been known as efficient catalysts for the production of formic acid with high faradaic efficiency close to 90%, still the environmental concerns for those toxic metals remain as a problem [4]. Therefore, the development of environmental friendly catalyst with high efficiency and selectivity is necessary. Moreover, if a certain catalyst can be used both in the reduction of CO<sub>2</sub> to formic acid and its oxidation to CO<sub>2</sub>, a unitized regenerative fuel cell based on the inter-conversion between CO<sub>2</sub>-C1 fuel (formic acid in this work) can be realized.

Therefore, this study aims to develop the catalyst materials that can be commonly used both in the reduction of CO<sub>2</sub> to formic acid and its revers reaction. We developed Sn-based alloy catalyst by electrodeposition and tested their activities toward the inter-conversion. All the electrolysis was conducted in the home-made H-type cell separated by a proton exchange membrane. The conversion products were analyzed using high performance liquid chromatography and electrochemical analysis including cyclic voltammetry. We have found that Sn-based alloy nano catalysts with certain composition were highly effective for the inter-conversion reactions and can be a potential candidate for the common electrode in the CO<sub>2</sub> based unitized regenerative fuel cell. Details will be given at the conference.

# Synthesis of Pt-CuO Composite via Electrodeposition Followed by Galvanic Replacement-Heat Treatment and Its Application to Non-Enzymatic Glucose Sensor

Seulki Kim, Changhyun Lee, Noseung Myung  
Department of Applied Chemistry, Konkuk University  
Chungju, Chungbuk 380-701, South Korea  
kelly2313@naver.com

Nanocomposite films of metal (Pt or Au) decorated CuO were synthesized via electrodeposition followed by a galvanic replacement reaction combined with heat treatment. First, Cu/Cu<sub>2</sub>O nanocomposite was electrodeposited under galvanostatic conditions using a 0.4 M CuSO<sub>4</sub> and 3 M lactate solution. pH of the electrolyte was adjusted to 9 using 5 M NaOH. Potential oscillations were observed during the galvanostatic deposition of the film, which indicated deposition of Cu/Cu<sub>2</sub>O layers. Cu/Cu<sub>2</sub>O films were subjected to a galvanic replacement reaction in solutions containing PtCl<sub>4</sub> or HAuCl<sub>4</sub> to produce Pt or Au modified Cu<sub>2</sub>O. Annealing of the Pt-or Au-Cu<sub>2</sub>O electrodes at 375°C for 10 hours in air resulted in Pt-or Au-CuO nanocomposite electrodes. The structure and morphology of the electrodes were characterized with EDX, XRD and SEM. The resulting electrode exhibited electrocatalytic activity for glucose. Effects of interferences were also studied in detail.

**Figure 1. Amperometric response to successive additions of 2 M glucose at a constant potential of 0.6V (vs. Ag/AgCl/3 M NaCl).**

# Anisotropic gold nanoplates – characterization and application in catalysis

Lidia Jagoda Opuchlik, Renata Bilewicz  
University of Warsaw, Faculty of Chemistry  
1 Louis Pasteur Street, 02093 Warsaw, Poland  
lgoralska@chem.uw.edu.pl

In recent years, Au nanoparticles have been center of attention of researchers. The progress in synthetic methods allowed to obtain not only spherical but also non-spherical nanoparticles e.g. plates, prisms, rods, wires and shells [1]. Anisotropic nanoparticles rise special interest due to their unique optical properties that result from possession of nonequivalent axes. The variety of shapes that can be obtained during the process of synthesis allow to improve the working efficiency of sensors due to the enhanced effective surface area and mass transport. Gold nanoparticles are interesting from the viewpoint of catalysis [2] but also as drug delivery systems and in thermal therapy of cancer [3].

We synthesized anisotropic gold nanoplates capped with thiosulfate via reaction of  $\text{HAuCl}_4$  with  $\text{Na}_2\text{S}_2\text{O}_3$  [4] and use them for the preparation of catalytic surfaces. UV – Vis Spectroscopy, DLS (size and zeta potential), and SEM were employed to characterize the NPs. GCE electrode was decorated with anisotropic gold nanoplates by drop casting and used in the oxygen reduction reaction (ORR). The reduction process includes two electrons and two protons and hydrogen peroxide is the final product. The measurements were held in three different supporting electrolytes: McIlvaine buffer of pH 5.5, 0.5M sulfuric acid and 0.1M KOH and the results were compared.

Fig.1 SEM image of GCE electrode modified with anisotropic gold nanoplates.

\*E-mail: mmorimit@mail.doshisha.ac.jp

RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> coated Ti anodes obtained by thermal decomposition are possible to significantly reduce the cell voltage up to 700 mV in metal electrowinning compared to traditional Pb alloy anodes and this voltage reduction is achieved by amorphization of the mixed oxide coating by low temperature thermal decomposition, resulting in high catalytic activity for oxygen evolution in acidic media [1]. Our recent studies on the kinetics of the amorphous RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> coating have revealed that the high catalytic activity is caused by the increase in active surface area of the amorphous coating, which consists of RuO<sub>2</sub> nano particles uniformly dispersed in amorphous Ta<sub>2</sub>O<sub>5</sub> matrix. This hybrid structure is self-assembled and is produced during thermal decomposition process. The active surface area influences on polarization of the mass transfer process for oxygen evolution, while there is little information on the electron transfer and overpotential of the amorphous coating. In this paper, we investigated the surface morphology, polarization, and Tafel slope of RuO<sub>2</sub> and RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> coatings obtained at different temperatures and Ru:Ta ratios for oxygen evolution in H<sub>2</sub>SO<sub>4</sub> solutions.

The anodes were prepared by thermal decomposition of precursor solutions containing Ru (III) and Ta (V). Ru:Ta mole ratios were 30:70, 50:50, or 100:0 (*i.e.*, RuO<sub>2</sub> only), and thermal decomposition was carried out at a temperature of 280 °C, 300 °C, 360 °C, or 500 °C. The characterization of the coatings was done with XRD, SEM, and EDX. Electrochemical measurements by cyclic voltammetry and linear sweep voltammetry were performed with a conventional three-electrode cell with KCl-saturated Ag/AgCl reference electrode and 2.0 mol/L H<sub>2</sub>SO<sub>4</sub> solutions.

Figure 1 shows Tafel slopes at different thermal decomposition temperatures and Ru mole ratios. Tafel slope was 65 mV in maximum in this study and was obtained with the RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> coating (Ru=30 mol%) prepared at 500 °C. In this case, well-grown RuO<sub>2</sub> particles were observed on the coating surface, while Tafel slope was down to 47 mV with the RuO<sub>2</sub> coating even at the same temperature. This seems to be reasonable, because RuO<sub>2</sub> is active for oxygen evolution, but Ta<sub>2</sub>O<sub>5</sub> is inactive. However, the difference in Tafel slope was also related to the surface morphology; both RuO<sub>2</sub> and RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> coatings showed a lot of large crystalline RuO<sub>2</sub> particles (200 nm or more), while the particle of about 20 nm co-existed only on the RuO<sub>2</sub> coating. The similar effect of Ru ratio on Tafel slope was also observed at other thermal decomposition temperatures. On the other hand, Tafel slope decreased with lowering thermal decomposition temperature at a fixed Ru ratio, and it was suggested that thermal decomposition temperature is important to the kinetics for oxygen evolution; the RuO<sub>2</sub> particle size strongly depends on the temperature, and Tafel slope is varied with the particle size and dispersibility of RuO<sub>2</sub>. The results obtained in this study further implied a possibility that the rate-determining step was changed by the particle size of RuO<sub>2</sub>.

\*E-mail: mmorimit@mail.doshisha.ac.jp

A titanium electrode coated with RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> mixture is obtained by thermal decomposition of a precursor solution containing Ru and Ta salts, and it has been revealed by our group that decreasing thermal decomposition temperature makes RuO<sub>2</sub> amorphous in the coating in which nano RuO<sub>2</sub> particles appears and has a high catalytic activity for oxygen evolution in acidic media [1]. In production of such metal oxides by thermal decomposition, the procedure and condition to prepare the precursor solution, *e.g.*, metal salt, solvent, mixing method, and temperature, affect the crystallographic and morphological property and electrochemical activity of the mixed oxide coating; *e.g.*, the literature has reported that the electrocatalytic property of crystalline RuO<sub>2</sub> coated Ti electrodes depends on ruthenium salts used in the precursor solution [2]. However, there has been little information on the effects of precursor solution on electrocatalysis of amorphous RuO<sub>2</sub>-based coatings for oxygen evolution in acidic aqueous solutions. This paper reports such effects on amorphous RuO<sub>2</sub>/Ti or RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub>/Ti electrodes.

RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub>/Ti and RuO<sub>2</sub>/Ti electrodes examined in this study were prepared by thermal decomposition at 280°C. RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> coatings used precursor solutions containing (a) RuCl<sub>3</sub> · nH<sub>2</sub>O and TaCl<sub>5</sub> or (b) Ru(NO<sub>3</sub>)<sub>3</sub> and TaBr<sub>5</sub> in 1-butanol or ethanol where the Ru ratio was 80 mol%. RuO<sub>2</sub> coatings were created with precursor solutions comprising Ru(NO<sub>3</sub>)<sub>3</sub> in distilled water or ethanol. XRD, SEM, and EDX were used for surface analysis of the coatings, and electrochemical measurements were conducted with 2.0 mol/L H<sub>2</sub>SO<sub>4</sub> solutions in a conventional three-electrode cell.

Figure 1 shows the cyclic voltammograms of RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub>/Ti electrodes prepared with the precursor solutions (a) and (b). The precursor solution (a) is the typical one that has been used in our group, while the solution (b) is modified with non-chloride source for Ru. XRD patterns of these two electrodes showed no clear diffraction peaks, indicating that the oxide coatings are amorphous. However, SEM observation revealed that both the coatings comprised flat areas and cracks and some RuO<sub>2</sub> particles were seen on the flat areas where the particle size of the electrode (a) was a few nm, while that was about 20 nm for the electrode (b). This suggests that the precursor solution affects the growth of RuO<sub>2</sub> during thermal decomposition. Because the active component for oxygen evolution is only RuO<sub>2</sub> and Ta<sub>2</sub>O<sub>5</sub> is inactive, the decrease in particle size of RuO<sub>2</sub> induces higher active surface area, resulting in lower polarization for oxygen evolution. On the other hand, RuO<sub>2</sub>/Ti electrodes produced with distilled water or ethanol in the precursor solutions showed no significant change in surface morphology and RuO<sub>2</sub> particle size, and the polarization curves were overlapped for them, indicating no difference in catalytic activity for oxygen evolution. More detailed results on the effects of metal salt and solvent on surface morphology and polarization will be given in this paper.

Fig.1 Cyclic voltammograms of RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub>/Ti anodes

Copper or zinc electrowinning use acidic aqueous solutions, and the anodic reaction is oxygen evolution for which lead alloy electrodes have been utilized for a long time. Recently an amorphous oxide coated titanium anode, MSA<sup>®</sup> [1], has been increasingly applied, in which titanium is appropriate to the substrate for such metal oxide coatings, because of its high corrosion resistance in strong acidic media by formation of non-conductive titanium oxide film. On the other hand, lead or lead alloy are cost-efficient compared to titanium and there has been no challenge to apply lead or lead alloy to the substrate of oxide coated anodes, especially with amorphous RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub>. In this paper, we report the preparation of RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> coatings on lead or lead alloy substrates and the results on surface analysis and electrochemical behaviors for oxygen evolution of the amorphous coatings.

RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> coatings were formed on lead or lead alloy substrates by thermal decomposition method as previously reported [1]; the precursor solution containing Ru(III) and Ta(V) was painted and heated at 280 °C, and the painting to heating process was repeated. A titanium substrate was also used for comparison. The characterization of the oxide coatings was done with XRD, SEM, and EDX. Cyclic voltammetry and constant current electrolysis were performed in 2.0 mol/L H<sub>2</sub>SO<sub>4</sub> solutions at 40 °C to evaluate polarization and stability of the amorphous oxide coating for oxygen evolution.

The oxide coatings were successfully created on lead or lead alloy substrates, in which the pretreatment of the substrate affected the obtained coating condition. EDX results presented Ru and Ta which were distributed on the whole of the coating surface, while XRD results presented the diffraction pattern of PbO, suggesting that the substrate was partly oxidized at 280°C and PbO was formed between the substrate and the coating like as the insulator because of its low conductivity. This was supported by the fact that cyclic voltammograms of RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub>/Pb or Pb alloy electrodes initially showed a quite low current even at the potential range in which oxygen evolution occurs on RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub>/Ti electrodes. Then the current density increased with the number of cycles, implying that PbO is oxidized to conductive PbO<sub>2</sub> during anodic potential scans. The stability of the oxide coating formed on Pb or Pb alloy was examined by constant current electrolysis, and the results were compared to that obtained with RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub>/Ti (Fig. 1). The analysis of the coating surface on Pb or Pb alloy after the electrolysis gave information on the reason for the voltage change shown in Fig. 1 and the degradation mechanism; the oxide coating works for oxygen evolution only within several hours for the coated Pb alloy electrode (a) and in about 40 hours for the coated Pb electrode (b), then the stable voltage seen at 2 to 2.2 V corresponds to oxygen evolution on PbO<sub>2</sub> after the RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> coatings are consumed and disappeared. The results suggest that the amorphous oxide coating formed on Pb or Pb alloy by thermal decomposition is unstable for oxygen evolution due to the oxidation of Pb.

Oxygen evolution in alkaline solutions is known as the anodic reaction of alkaline water electrolysis or the charge reaction at the positive electrode of air secondary batteries, while the material possible to use for this gas evolution is limited; *e.g.*, nickel alloys are only commercialized for alkaline water electrolysis, but the positive electrode of the air secondary battery is still requiring a novel material for oxygen evolution and reduction. The difficulty to find an appropriate material is caused from highly corrosive environment of alkaline solutions to metals, alloys, oxides, and other conductive compounds. Under the situation, one of the authors of this paper has revealed that crystalline IrO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> coatings obtained by thermal decomposition have a high durability for electrolysis at 1 A/cm<sup>2</sup> in 4 mol/L NaOH solutions [1] and has also demonstrated that amorphous IrO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> coatings prepared at low thermal decomposition temperature has lower oxygen overpotential than crystalline ones [2]. Therefore, this work focused on the effects of Ir:Ta composition of amorphous IrO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> coatings on oxygen evolution in alkaline solutions. Amorphous IrO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> coatings at different mole ratio were prepared on titanium substrates and analyzed by SEM observation, and the oxygen evolution behaviors in KOH solutions were investigated by cyclic voltammetry and constant electrolysis.

A titanium plate was used as a substrate to create the amorphous IrO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> coatings by thermal decomposition of precursor solutions containing Ir(IV) and Ta(V) in 1-butanol. The Ir mole ratio in the precursor solution was 40 mol%, 60 mol%, or 80 mol%, and thermal decomposition was carried out at 360 °C. The crystallographic structure, surface morphology, and Ir:Ta ratio were analyzed by XRD, SEM, and EDX. Electrochemical measurements were conducted using a three-electrode cell or a two-electrode cell with 5.0 or 6.0 mol/L KOH solutions at 40 °C. The reference electrode was an Hg/HgO electrode, and the counter electrode was a platinum plate.

All coatings prepared on titanium in this work were amorphous, because no diffraction peak was found that was independent of Ir mole ratio. The surface morphology of such amorphous coatings was basically smooth areas and cracks, while the electrochemical behaviors were influenced on the Ir mole ratio. The double layer charge measured by cyclic voltammetry increased with increasing Ir mole ratio, and the voltammograms for oxygen evolution revealed that the catalytic activity was enhanced with more Ir in the coating. This is reasonable, since IrO<sub>2</sub> is catalytic, but Ta<sub>2</sub>O<sub>5</sub> is non-catalytic to O<sub>2</sub> evolution. The constant current electrolysis was also performed to examine the stability of the amorphous IrO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> coatings. The results obtained at 50 mA/cm<sup>2</sup> revealed that the amorphous coatings of Ir=80 mol% kept stable voltage over 100 hours, although the voltage increased earlier with the coatings of Ir=40 mol% and 60 mol%. EDX analysis of the coatings before and after the electrolysis indicated that the degradation of the coating occurred with tantalum consumption, which is faster than iridium on the coatings of Ir=40 mol% or 60 mol%, suggesting that Ta<sub>2</sub>O<sub>5</sub> was predominantly consumed for oxygen evolution in alkaline solutions which is quite different from the results obtained in acidic aqueous solutions.

# Oxygen Evolution Reaction Behavior of Vapor Grown Carbon Fiber and The Loading Effect of LaMnO<sub>3</sub> in KOH Aqueous Solution

Makoto Eto, Taro Kinumoto, Kohei Ono, Tomoki Tsumura, Masahiro Toyoda

Dept. of Appl. Chem., Graduate School of Eng., Oita Univ., 700 Dannoharu, Oita, 870-1192, JAPAN

Oxygen evolution reaction (OER) in aqueous solutions is the discharge reaction for air batteries such as metal|air and metal hydride|air (MH|air) batteries. If the carbonaceous material is used as the cathode materials, the corrosion of carbonaceous materials would be serious because the standard potential of carbon oxidation reaction (COR at 0.27 V) is less negative than that of OER (1.23 V). Ross and Sokol studied the OER in alkaline solution at 50 °C using acetylene black, which is commercially available carbonaceous material, and they reported that the current efficiency of OER ( $\varepsilon_{\text{OER}}$ ) is lower than that for COR below 550 mV vs. Hg|HgO. [1] On the other hand, vapor grown carbon fiber (VGCF, SHOWA DENKO K.K.) is one of the high crystalline carbonaceous materials; thereby,  $\varepsilon_{\text{OER}}$  is expected to be high for application to air batteries. Then, we have investigated  $\varepsilon_{\text{OER}}$  of VGCF by *in-situ* measurement using a dissolved oxygen sensor [2]. In this presentation, the effects of the concentration of KOH and the loading of LaMnO<sub>3</sub> (typical OER catalyst) on  $\varepsilon_{\text{OER}}$  are reported.

The loading of LaMnO<sub>3</sub> on VGCF (LaMnO<sub>3</sub>/VGCF) was carried out by a co-precipitation method [2]. VGCF or LaMnO<sub>3</sub>/VGCF was dispersed on Ti substrate and fixed with a thin film of anion-exchange-membrane (ionomer solution: AS-4, TOKUYAMA K.K.) Then, those were employed as the working electrode. OER study was carried out by chronoamperometry every 0.05 V between 1.40 ~ 1.70 V. Holding time is set at 10 hours. Hg / HgO electrode and a Ni mesh were employed as the reference electrode and as the counter electrode, respectively. The electrolyte solution was 0.1 or 1.0 mol dm<sup>-3</sup> KOH aqueous solution to simulate the condition of MH|air battery. A dissolved oxygen sensor (DO meter, InLab<sup>®</sup> OptiOx, METTLER TOLEDO) was placed near the working electrode to measure the amount of oxygen production in the electrolyte [2].

Figure 1 shows the steady – state polarization curves and amounts of oxygen produced in the electrolyte upon application of potential for VGCF. In the case of 0.1 mol dm<sup>-3</sup> KOH used, both of dissolved oxygen and current were increased above 1.65 V; on the other hand, those were increased above 1.60 V in 1.0 mol dm<sup>-3</sup> KOH used. These results show that the onset potential for OER becomes to be low by increasing in KOH concentration.

Figure 2 shows  $\varepsilon_{\text{OER}}$  of VGCF and LaMnO<sub>3</sub>/VGCF. Here,  $\varepsilon_{\text{OER}}$  was estimated from the ratio between the electric quantity ( $Q_{\text{CA}}$ ) used during the chronoamperometry measurements and the quantity ( $Q_{\text{O}_2}$ ) that was responsible for the oxygen production ( $N$ ).  $\varepsilon_{\text{OER}}$  of VGCF is depended on KOH concentration; unfortunately, it reaches even at *ca.* 17.5% in 1.0 mol dm<sup>-3</sup> KOH solution. The onset potential for OER of LaMnO<sub>3</sub>/VGCF is lower than for VGCF and  $\varepsilon_{\text{OER}}$  is increased by loading with LaMnO<sub>3</sub>. However,  $\varepsilon_{\text{OER}}$  tends to decrease at higher potential region as similar to the result of VGCF.

Fig. 1 Steady – state polarization curves and amounts of oxygen for VGCF in 0.1 M and 1.0 M KOH aq.

Fig. 2 Current efficiencies for OER of VGCF and LaMnO<sub>3</sub> / VGCF.

A metal/air secondary battery has a high theoretical energy density, and the positive electrode reaction is changed with the negative electrode and the electrolyte. In case of metal hydride/air secondary battery utilizing the negative electrode comprising hydrogen storage alloys and alkaline aqueous solutions as the electrolyte, the positive electrode should work for oxygen reduction during discharge and oxygen evolution during charge [1]. The positive electrode is a gas-diffusion electrode and a bi-functional catalyst, with which oxygen reactions should occur at three-phase interfaces of catalyst/air/alkaline solution and at a low polarization, is needed. However, oxygen reduction has a high overpotential over 300 mV and makes the loss of discharge voltage; thereby the voltage efficiency and the practical energy density are still low. Polarization for oxygen evolution should be also minimized, and our group has recently revealed that RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> mixed oxide obtained by thermal decomposition, especially the amorphous mixed oxide prepared at low temperature, has a high catalytic activity for oxygen evolution from alkaline solutions [2]. This novel catalyst would be one of the candidates for the bi-functional catalyst of the metal/air secondary battery, although no information has been reported on the electrochemical behaviors for oxygen reduction in alkaline solutions. In this work, thin RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> films were prepared on disk and the polarization behaviors for oxygen reduction were investigated with rotating disk electrode (RDE) and compared to the results obtained with platinum.

RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> mixed oxides were prepared by thermal decomposition of precursor solutions which comprised 1-butanol solution containing Ru (III) and Ta (V) ions. One side of a titanium disk was painted with the precursor solution and heated at a temperature of 300 °C or 500 °C to make a thin oxide film, which was analyzed by XRD and SEM. Electrochemical measurements were carried out using a three-electrode cell with RDE and 6 mol/L KOH solutions. The polarization behaviors were measured in the solution after treating with N<sub>2</sub> and then with O<sub>2</sub>. Oxygen reduction current was obtained by subtracting the polarization curves obtained under N<sub>2</sub> and O<sub>2</sub> conditions. A platinum disk of the same size as the titanium one was also used as the working electrode for comparison of the catalytic activity to RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> mixed oxides at different rotation rates.

XRD and SEM results showed that the crystallinity of RuO<sub>2</sub> reduced with decreasing thermal decomposition temperature and large aggregated RuO<sub>2</sub> particles seen in the oxide film prepared at 500 °C changed to uniformly dispersed nano-particles at 300 °C. Polarization measurements with those films presented oxygen reduction current starting at about 0 V vs. Hg/HgO reference electrode in 6 mol/L KOH. The diffusion-limited current for oxygen evolution was also observed with RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> films prepared at 300 °C and 500 °C and increased with increasing rotating rate. The catalytic activity for oxygen reduction for the mixed oxide of 300 °C was higher than that of 500 °C, which is reasonable because the former has nano RuO<sub>2</sub> particles which provide more active surface areas. Compared to platinum, RuO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> (300 °C) still showed a higher catalytic activity for oxygen reduction.

## Abstract

Electrochemical capacitors have been fabricated using graphene nanosheets (GNs) modified with carbon nanotubes (CNTs) as electrode materials and LiClO<sub>4</sub>/propylene carbonate as organic electrolyte. A homogenizing method is used to insert CNTs into the GNs, forming three-dimensional carbon framework. The electrochemical properties of three-dimensional carbon composites are characterized by cyclic voltammetry, galvanostatic charge-discharge cycling, and *ac* impedance spectroscopy in the LiClO<sub>4</sub> electrolyte.

This improved performance can be assigned to that the presence of CNTs assists not only more electro-active sites on the GNs surface but also better for Li ions diffusion and electrolyte wetting in the carbon framework. The energy density of CNT/GN-based electrochemical capacitor can reach as high as 15 Wh kg<sup>-1</sup> at a power density of 2,500 W kg<sup>-1</sup>, analyzed by the Ragone plot. Accordingly, the CNT/GN hybrid composite can be considered as a promising electrode material for Li-ion electrochemical capacitors due to its low cost, high performance, and easy fabrication.

Increased energy demands provide opportunities for the development of new technologies for energy conversion and storage device. Water splitting technology, a promising approach, has been investigated for many years to the storage of electrical energy. However in large scale production of the oxygen evolution reaction (OER) for water splitting occurs with large overpotential due to the sluggish kinetics and complex four electron transfer process. So to accelerate the reaction rate and lower the overpotential, an active OER catalyst is necessary [1]. So far, the noble metal catalysts such as Pt, Ru and Ir have shown excellent OER activity and durability. Despite of their good catalytic activity, high cost and scarcity limit their application. Thus, a material with high performance, inexpensive and eco-friendly design is required.

In this study, we have synthesized an inexpensive and highly active OER electrocatalyst,  $\text{Co}_3\text{V}_2\text{O}_8$  with different morphologies using the electrospinning technique and followed by pyrolysis [2]. The OER potential of 1.52 and 1.56V Vs RHE in 1M aqueous KOH electrolyte was observed for  $\text{Co}_3\text{V}_2\text{O}_8$  with nanotube and nanoparticle, respectively morphology. The synthesis and electrocatalytic properties of these materials will be discussed in this presentation.

Carbon-based materials as electrode materials are widely used for the energy storage application of vanadium redox flow batteries (VRFBs). However, the electrochemical activity of the carbon-based material was poor, which limits the electrochemical performance of VRFB. Some methods can improve the electrodes activity of carbon-based materials. For example, the functionalization method enhances the functional groups on the surface of electrode [1, 2], and nanostructure control method tunes the surface morphology of electrode [3].

In this work, we try to enhance the electrochemical activity of carbon felt by using the functionalization method, making the high performance and high efficiency of carbon felt electrode for VRFBs. The functionalized carbon felt electrode performs a good electrochemical activity of  $\text{VO}^{2+}/\text{VO}_2^+$  redox reaction in a three-electrode method test. By employing the functionalized carbon felt electrodes in the both electrodes of VRFB, it shows good coulombic efficiency, voltage efficiency, and energy efficiency which are around 93.8%, 81.1% and 76.1%, respectively.

## Introduce

For the hydrogen society without CO<sub>2</sub> emission, it is necessary to produce hydrogen using fluctuating power supply from renewable energy. In order to obtain the active and durable anode for alkaline water electrolysis (AWE) against fluctuating power, we have already reported that a nickel with lithiated NiO coating showed high activity and durability under potential cycling<sup>1</sup>. Because of good electric conductivity and activity, nickel containing perovskite-type oxides which sintered at high temperature are regarded as candidate materials, but the examination of the durability is not accomplished<sup>2</sup>. Therefore, in this study, we have investigated the oxygen evolution reaction (OER) activity and durability of a LaNiO<sub>3</sub>/Ni as an AWE anode using fluctuating supply.

## Experimental

The LaNiO<sub>3</sub> powder was prepared by the thermal decomposition of precursor containing lanthanum nitrate hexahydrate and nickel acetate tetrahydrate at 1073 K for 12 h in air<sup>3</sup>. Then, a Ni electrode which was coated by LaNiO<sub>3</sub> with polyvinyl alcohol (PVA) was sintered at 773-973 K. A process of dipping of the electrode into the precursor, drying, and sintering at 773 K was repeated for six times. Finally, the electrodes were heat-treated for 1 h at 1073 K in air to obtain a LaNiO<sub>3</sub>/Ni (LNO\_773, 873, or 973 of sintering temperature) as a working electrode. The LNO was analyzed by XRD before and after electrochemical measurements.

The electrochemical measurements were carried out at 30±1 °C, using with RHE and Ni coil as a reference electrode and counter electrode, respectively. Potential cycle was carried out for 25,000 cycles between 1.0 and 1.8 V with scan rate of 100 mVs<sup>-1</sup>. The catalytic activity for the OER was evaluated by slow scan voltammetry between 0.5 and 2.0 V with scan rate of 5.0 mVs<sup>-1</sup> during the potential cycling.

## Results and discussions

Figure 1 shows the OER currents at 1.6 V vs. RHE on the LNOs with various sintering temperature during potential cycling. The OER currents on the LNOs were stable during potential cycling. In contrast, the OER current on Ni decreased dramatically with the increase of cycle, even the initial current of OER on Ni was much larger than that on the LNOs in this study<sup>1</sup>.

OER currents at 1.0 mA cm<sup>-2</sup>, as an index of the OER activity, of the LNOs were slightly higher than that of Ni, and Ni with lithiated NiO coating before potential cycling, but they were lower than that of Ni after potential cycling. Therefore, the OER activity of the LNOs should be almost the same to Ni.

According to XRD analysis, Ni(OH)<sub>2</sub> formed on the Ni electrode after potential cycling. This is attributed the degradation of the OER currents on Ni. In the case of the LNOs after potential cycling, LaNiO<sub>3</sub> and Ni were detected as same as that before electrochemical measurements.

From above results, LaNiO<sub>3</sub>/Ni would be an alternative anode electrode for alkaline water electrolysis using with electric power which is produced from renewable energy.

Fig. 1 OER current on LaNiO<sub>3</sub>/Ni and Ni at 1.6 V vs. RHE during potential cycling at 30 °C.

# Screening of Ru-based Electrocatalysts for Oxygen Reduction by Scanning Electrochemical Microscopy

Yu-Ching Weng, Wei-Fen Xiong  
*Department of Chemical Engineering*  
*Feng Chia University, Taichung, Taiwan, 40724*  
*ycweng@fcu.edu.tw*

Oxygen reduction reaction (ORR) electrocatalyst is one of the most hot issues in the academia and industries due to its application in polymer electrolyte membrane fuel cells (PEMFCs). In this report, a high-throughput screening technique based on scanning electrochemical microscopy (SECM) with a tip-generation–substrate-collection (TG–SC) mode was applied to identify potential electrocatalysts for ORR. Bimetallic ruthenium (Ru-M, M = V, Cr, Mn, Fe, Co, Ni, Cu and Zn) based chalcogenide (S, Se, Te) arrays were fabricated and screened for activity as ORR electrocatalysts. The potential electrocatalysts were then characterized by SEM, EDX, XRD and XPS. The catalytic activity of potential electrocatalysts were further examined during cyclic voltammetric scans of the substrate with a tip close to the substrate. The quantitative rate of ORR on the candidate substrates was determined for different substrate potentials from SECM approach curves by fitting to a theoretical model. The ruthenium based electrocatalysts that showed high activity for ORR were identified in this work.

# Fundamental Studies on Electrochemical Oxidative Properties of a Gold Nanoparticle-Attached Palladium Electrode

oyama.munetaka.4m@kyoto-u.ac.jp*

Metal nanoparticles (NPs) have been attracting active attention as functional units for electrode modifications because they can change the electronic communications on the conductive materials. If we would like to attach gold NPs (AuNPs) on the ITO surfaces, the functional bridging reagents such as (3-mercaptopropyl)-trimethoxy-silane or charged polymers have been adopted.

While many successful results have been obtained using the bridging reagents, our group is proposing a simple methodology to attach AuNPs on the ITO surfaces [1]. Namely, by applying a seed-mediated growth method, which was originally developed for synthesizing metal nanorods in aqueous solution [2], to the surface modification, the crystal growth of AuNPs on the ITO surfaces could be performed from the Au nano-seed particles adsorbed on the ITO with keeping adhesion contacts. As the results, some successful electroanalysis could be performed using thus prepared AuNP-attached ITO electrodes [3].

While we have been utilizing Au nano-seed particles followed by the nanostructural growth in growth solutions, only the attachment of Au nano-seed might change the electrochemical characteristics of the base conducting materials. Although the effects of Au nano-seed on ITO electrodes were relatively scarce, we explored the combinations of Au nano-seed particles with bulk metal electrodes, such as Au, Pt, Ni and Pd electrodes.

Consequently, in the cases of Au and Pt electrodes, no remarkable changes in electrochemical responses were observed. However, interesting changes in electrochemical responses were observed for an AuNP-modified Ni electrode [4]. Furthermore, as an unusual phenomenon, we could observe the electrocatalytic oxidation of water in alkaline solutions with an AuNP-modified Pd electrode [5].

In the latter case of the AuNP-modified Pd electrode, it is characteristic that the oxidation peak is observed with an enhanced current magnitude, implying the electrocatalytic oxidation. However, the reproducibility of the electrochemical responses was not very good. Therefore, we explored some factors to affect the oxidative responses. As the result, it was found that the polish of a base Pd electrode was quite important to observe oxidative peaks. As well, the polish should be carried out just before immersing the base electrode into a solution of Au nano-seeds.

Also, we studied the effects of NaBH<sub>4</sub>, which is used to form Au nano-seed particles as a reducing reagent, on the redox properties of a Pd base electrode. As the result, formed hydrogen in the reaction of NaBH<sub>4</sub> was found to make appearance of the oxidative responses, which are similar to those observed with an AuNP-modified Pd electrode. This result implies complex aspects of surface redox reactions on Pd in alkali solutions.

Some trials to make clear the mechanisms of the appearance of the oxidative currents will be presented at the meeting.

# Polarization for a toluene hydrogenation electrolyzer with various concentration of toluene feed

Yuki sawaguchi<sup>1)</sup>, Yasutomo Takakuwa<sup>1)</sup>, Kensaku Nagasawa<sup>1)</sup>, Yuji Kohno<sup>1)</sup>,  
Koichi Matsuzawa<sup>1)</sup> and Shigenori Mitsushima<sup>1, 2)</sup>

<sup>1)</sup> Green Hydrogen Research Center, <sup>2)</sup> IAS, Yokohama National University, 79-5 Tokiwadai, Hodogaya-ku, Yokohama 240-8501, Japan,

## Introduction

Usage of renewable energy get a lot of attention for a way to sustainable society. To supply of renewable energy on demand, large-scale of energy for storage and transportation is needed. We pay attention the organic hydride especially toluene-methylcyclohexane system as a carrier for energy storage and transportation. Direct electrohydrogenation electrolyzer for toluene using renewable energy has been under development applying PEFC and industrial electrolysis technology as a high energy conversion efficiency technology [1]. To improve efficiency of the electrolyzer, factorial analysis for polarization is needed.

In this study, a method of factorial analysis with reversible hydrogen electrode (RHE) has been developed to evaluate the polarization of electrolyzer for direct hydrogenation of toluene.

## Experimental

An anode was DSE<sup>®</sup> (Permelec Electrode Ltd.) electrode for oxygen evolution. A cathode was 0.5 mg cm<sup>-2</sup> of PtRu/C catalyst (Tanaka Kikinzoku Kogyo) coated on a carbon paper (SGL Carbon) electrode that was assembled on a Nafion<sup>®</sup> (DuPont) membrane that was hydrophilized for anode side. Nominal electrode area was 11.3 cm<sup>2</sup>. To guard breaking membrane, 25  $\mu$ m of a spacer was put between anode and electrolyte membrane, and back pressure of anode side was 500 mmAq higher than cathode side. 10 ml min<sup>-1</sup> of sulfuric acid and 5 ml min<sup>-1</sup> of toluene (TL)/methylcyclohexane (MCH) were fed to anode and cathode compartment, respectively. Concentration of TL was in the range from 5 to 100 %. A Luggin capillary for a RHE was placed near the anode. Polarization was evaluated with constant cell voltage measurement at 1.3~2.5 applied cell voltage, 60 °C. Resistance of electrolyte evaluated by AC impedance at 10<sup>5</sup>~10<sup>-1</sup> Hz.

## Results and discussion

Figure 1 shows the IR corrected potential-current curves of constant cell voltage measurement with various concentration of TL feed. Dashed dotted line shows the theoretical potential of 0.15 V vs RHE for anode and 1.23 V vs RHE for cathode. The polarization curves for anode and cathode were almost the same even lower TL concentration up to 100 mA cm<sup>-2</sup>. The anode and cathode overpotentials were 0.32-0.35 and 0.19-0.24 V at 10 mA cm<sup>-2</sup>, respectively. At 100 mA cm<sup>-2</sup>, they were 0.46-0.53 and 0.28-0.41 V, respectively. Therefore, the anode overpotential was significantly larger than that of the cathode, but the difference between anode and cathode decreased with the increase of current density. The anode overpotential was hardly affected by TL concentration. On the other hand, the cathode overpotentials increased with decrease of TL concentration and they significantly increased in the higher current density. Simultaneously, hydrogen evolution reaction was observed, which should correspond to lack of TL mass transfer to the catalyst.

## Acknowledgment

This work was supported by Cross-ministerial Strategic Innovation Promotion Program (SIP), “energy carrier” (Funding agency: JST). The anode was supplied by Permelec Electrode Ltd. We appreciate the person concerned them.

## Abstract

Carbon dioxide has received considerable attention as an available and abundant source in synthesis of organic compounds. But the large overpotential is required to convert of this inert molecule to a reactive particle for participating in a chemical reaction [1]. In order to more convenient convert of unreactive CO<sub>2</sub> molecule to desired products in electrochemical synthesis, different molecular and a number of transition metal complexes have been used as electron transfer mediators [2]. Complex of [Ni<sup>II</sup>(Me<sub>4</sub>-NO<sub>2</sub>Bzo)<sub>2</sub>[14]tetraeneN<sub>4</sub>)] has an excellent electrocatalytic activity for CO<sub>2</sub> reduction [3]. In our previous work, application of [Ni<sup>II</sup>(Me<sub>4</sub>-NO<sub>2</sub>Bzo)<sub>2</sub>[14]tetraeneN<sub>4</sub>)] complex for cyclic carbonates electrosynthesis was reported [4].

Cinnamic acid is used in certain pharmaceuticals and also in the manufacturing of different esters [5]. In this work, the [Ni<sup>II</sup>(Me<sub>4</sub>-NO<sub>2</sub>Bzo)<sub>2</sub>[14]tetraeneN<sub>4</sub>)] complex was used for electrocatalytic reduction of CO<sub>2</sub>. Then, cinnamic acid was electrosynthesised by reaction of the reduction product of CO<sub>2</sub>, (CO<sub>2</sub><sup>•-</sup>), with phenylacetylene. The results indicate that the cathodic current of the complex was increased in the presence of CO<sub>2</sub> and the anodic peak current was disappeared. Also, a rise in the electrocatalytic current of CO<sub>2</sub> reduction was observed after addition of phenylacetylene. Controlled potential coulometry was carried out in an undivided glass cell equipped with a gas inlet and outlet with a graphite rod as the cathode, a platinum plate as the anode and Ag/Ag<sup>+</sup> (0.01 M AgNO<sub>3</sub> in 0.1 M TBAP acetonitrile solution) as the reference electrode. After separation of products by liquid-liquid extraction and preparative TLC, the spectral characterization, FTIR, <sup>1</sup>H and <sup>13</sup>C NMR, demonstrated cinnamic acid is the main product of electrolysis.

In the present work the graphene supported PtCoMo catalysts were prepared by a simple and cost-effective galvanic displacement technique. At first, the Co or CoMo was deposited on the surface of graphene powder via electroless deposition. Then, the Pt crystallites were deposited on the prepared Co/graphene or CoMo/graphene catalysts by their immersion into platinum-containing solution for various time periods. The electrocatalytic properties of the Co/graphene, CoMo/graphene and PtCoMo/graphene catalysts towards the oxidation of borohydride and methanol in an alkaline medium were investigated by means of cyclic voltammetry and chrono-techniques.

The electrocatalytic activity values of the PtCoMo/graphene catalysts prepared under various conditions are compared and discussed on the basis of electrochemical data.

# Ruthenium Nanocomposites for Electrochemical Detection: Design and Modification of Graphene Electrodes for Biosensors

ausra.baradoke@ftmc.lt

Electrochemical detection is a promising approach for the next generation of diagnostic methods [1]. We used innovative Screen-Printed Graphene Electrodes (SPGPHEs), because of its high thermal and electric conductivity [2] and nanoparticles, because of catalytic properties, which can be used for increasing sensitivity and selectivity of detection.

For investigation, graphene electrodes were modified with ruthenium nanoparticles synthesized in autoclave. Triangular ruthenium nanoparticles prepared using hydrothermal synthesis method [3]. Formed ruthenium nanoparticles were analyzed using transmission electron microscope and the modified surface was analyzed using scanning electron microscope (SEM) (Fig. 1). Cyclic voltammograms of  $\beta$ -Nicotinamide (NADH) on bare SPGPHE and SPGPH/PoPD/RuNPs modified electrode showed that the electrocatalytic current increased significantly (40%) in case that the RuNPs were present onto the electrode surface.

A remarkable catalytic oxidation current at the modified electrode occurred at ca. 0V, which negatively shifted higher than 400 mV, compared with that at bare electrode (Fig. 2). A study of the electrocatalytic behavior of NADH oxidation on the SPCE/GPH with RuNPs in phosphate buffer (PBS) was carried out in this work. We found that the current of NADH oxidation increases (Fig. 2) and peak potential shifts to lower potential, when we use Ru nanoparticles. This system can be used for biosensors, because ruthenium nanoparticles increase the active surface area and provide electron transfer with strong catalytic properties.

Fig. 1. SEM image of graphene (SPGPH) surface modified by ruthenium nanoparticles.

Fig. 2. Cyclic voltammograms of SPGPH electrodes with and without RuNPs in the presence of 5 mM NADH in 0.1 M PBS (pH 6.8), scan rate: 50 mVs<sup>-1</sup>.

# REDOX PROPERTIES AND ELECTROCATALYTIC OXYGEN REDUCING PERFORMANCES OF VARIOUS NOVEL METAL PHTHALOCYANINES

Zuhal Yazar,<sup>a</sup> Mehmet Pişkin,<sup>b</sup> Zafer Odabaş,<sup>a</sup> Ali Rıza Özkaya<sup>a</sup>

<sup>a</sup>Marmara University, Department of Chemistry, Istanbul, Turkey

<sup>b</sup>Çanakkale 18 Mart University, Çanakkale Vocational School of Technical Sciences, Çanakkale, Turkey  
aliozkaya@marmara.edu.tr

Phthalocyanine (Pc) derivatives have been receiving increasing interest due to their applicability in various advanced technological areas such as energy conversion and/or storage devices, photodynamic therapy, photovoltaic cells, sensors, electrochromic materials and catalysis. The applicability of these compounds in the mentioned areas strongly depends on their electronic and electrochemical properties. Thus, the determination of the electron transfer properties of novel Pc derivatives is highly important in term of the identification of possibility of the usage in these areas.

The electrocatalytic activity of compounds for dioxygen reduction has vital importance since this reaction, occurring at one of the electrodes of both fuel cells and metal-air batteries, has slow electrode kinetics. The studies in literature showed some type of Pc complexes display high catalytic activity for dioxygen reduction.<sup>1</sup> This work involves the identification of redox properties of various novel mononuclear tetra-alpha substituted metal Pcs by voltammetric and *in situ* spectroelectrochemical measurements. It also includes the investigation of their electrocatalytic performances for dioxygen reduction by dynamic voltammetry measurements, with the aim of determining their suitability for usage as oxygen reduction catalyst in energy conversion and/or storage devices.

**Fig.1.** Molecular structure of mononuclear tetra-alpha substituted metal Pc template.

jaeyoung@gist.ac.kr

In recent years, reducing anthropogenic  $\text{CO}_2$  is of great interest because of its detrimental effect on environmental ecosystem. As one of possible solutions for the  $\text{CO}_2$  problem, electrochemical reduction of  $\text{CO}_2$  using metal oxide catalyst draws a considerable attention [1-3]. Specifically adsorbed anions have a crucial role in electrochemical reaction, often affecting directly the structure of electrode material and heterogeneous reaction environment near the electrode surface [4]. Such various known features can be also utilized in the electrochemical reduction of  $\text{CO}_2$ . We report the superior  $\text{CO}_2$  electrolysis on the oxygen-evacuated  $\text{Cu}_2\text{O}$  with aid of  $\text{Cl}^-$ . Under the electrolytic system, high multi-carbon fuels (e.g.,  $\text{C}_2\text{H}_5\text{OH}$ ,  $\text{C}_3\text{H}_7\text{OH}$ , and even  $\text{C}_4\text{H}_{10}$ ) are generated with obviously high total faradaic efficiency and stably for long time period. One would attribute the remarkable electrocatalysis to synergism between the  $\text{Cu}_2\text{O}$  and  $\text{Cl}^-$  such as suppression of proton adsorption on the surface of electrode leading to low hydrogen evolution reaction and enhanced  $\text{Cu}_2\text{O}$  preservation. From our studies, we provide that preferential production of high carbon number molecules can be achieved on the use of Cu-based catalysts and the interesting results opens up further opportunities of  $\text{CO}_2$ -fed chemical plants.

In recent years, Li air secondary batteries (LABs) have been attracted much attention as next-generation energy storage because of the possibility of greatly higher energy density ( $> 500 \text{ Wh kg}^{-1}$ ) than that of Li-ion batteries (LIBs). However, the LAB systems have some serious problems to be solved before the commercialization; e.g. suppression of Li metal dendrite at the anode, improvement of durability of electrolyte solutions against electrochemical oxidation, preparation of high performance air electrode catalysts at the cathode, etc. Especially for the air electrode catalysts, both catalytic activities for  $\text{O}_2$  reduction reaction (ORR) and  $\text{O}_2$  evolution reaction (OER), and also durability for electrochemical oxidation are demanded. In this study, we prepared two kinds of Mn oxide nanosheet (MnNS)/nanocarbon (carbon nanotube (CNT) or Ketjen black (KB)) composite materials, i.e. MnNS/CNT and MnNS/KB, and evaluated the electrochemical properties of ORR and OER activities along with the durability.

The MnNS was synthesized by single-step solution method [1] by adding the mixture of 30wt%  $\text{H}_2\text{O}_2$  (2 g) and 0.6 M TMAOH (24 mL) to 0.3 M  $\text{MnCl}_2$  (20 mL), and then stir during one night at 500 rpm to obtain ca.  $8.7 \text{ g L}^{-1}$  MnNS colloidal dispersion. 20 mL of the MnNS colloidal dispersion was mixed with proper amount of nanocarbon (CNT or KB) dispersed in ethanol (50 mL) under ultrasonic vibration for 90 min, and then 0.1 M LiCl (40 mL) was gradually dropped to the colloidal dispersion to form the composite materials. After being filtered, the composites were heat-treated at  $400^\circ\text{C}$  for 5 h in Ar atmosphere. Characterization of the samples was conducted by X-ray diffraction (XRD) analysis and transmission electron microscope (TEM) observation. The ORR and OER activities were examined by hydrodynamic voltammetry (HV) using a rotating ring-disk electrode (RRDE) in 0.1 M KOH at  $50^\circ\text{C}$  [2].

Fig. 1(a) and (b) show the TEM images of MnNS/CNT and MnNS/KB composites, respectively. In both samples, the each component of MnNS, CNT and KB were homogeneously mixed and seemed to have good contact between MnNS and nanocarbons. From the result of HV curves for the composites (Fig. 2(a)), the MnNS/KB exhibited a higher ORR activity than the MnNS/CNT and only MnNS. This indicates that the ORR activity of MnNS was effectively enhanced by compositing with KB. From a very large ORR current for the MnNS/KB, it is considered that the KB was successfully inserted between MnNSs and constructed suitable electron paths for the MnNS. On the other hand, for the OER, (Fig. 2(b)), a higher OER current was also attained for the MnNS/KB compared to that for the MnNS/CNT. However, the onset potentials of MnNS/KB and KB were too negative below 1.23 V, implying the OER current included oxidation current of KB. The further discussion will be presented at the meeting.

We gratefully thank to Tokuyama Co. for providing alkaline ionomer binder. This work was supported by JST "A Tenure-track Program" and JSPS "KAKENHI" (25870899) from MEXT, Japan.

Nanomotors are nanoscale devices propelled by the electrocatalytic decomposition of a chemical fuel [1]. Motion control of nanomachines are currently the subject of intense interest due to their potential applications in nanomachinery, nanomedicine, nanoscale transport [2]. In this study, we prepared a TiO<sub>2</sub>/Pt/Au nanomotor, and tried to control its driving speed by switching ON/OFF of the ultraviolet light irradiation.

The TiO<sub>2</sub>/Pt/Au nanomotor was prepared by a sequential electrodeposition of the gold, platinum, titanium dioxide segments into a porous alumina membrane template (Catalog no. 6809–6022; Whatman, Maidstone, U.K.). The titanium dioxide segment was prepared according to a procedure reported by S. Karuppuchamy et al [3]. A solution containing 0.06 mol dm<sup>-3</sup> TiOSO<sub>4</sub>, 0.09 mol dm<sup>-3</sup> hydrogen peroxide and 0.3 mol dm<sup>-3</sup> potassium nitrate was used as plating solution. The electrode potential was set at -1.1 V vs. Ag/AgCl for 5 min. Then, the aluminum membrane was sintered at 500 °C for 1 h. The sputtered silver layer and sacrificial silver layer was dissolved using a 2 mol dm<sup>-3</sup> nitric acid. The membrane was then dissolved in a 3 mol dm<sup>-3</sup> NaOH solution for 1 h to completely release the nanowires. Movement of TiO<sub>2</sub>/Pt/Au nanomotor was observed in 5 % H<sub>2</sub>O<sub>2</sub> solution with and without ultraviolet (UV) light irradiation.

Figure 1 shows a field emission scanning electron microscopy (FE-SEM) image of a TiO<sub>2</sub>/Pt/Au nanomotor. This nanomotor's length and diameter were about 4.2 μm and 200 nm, respectively. Figure 2 shows the average speeds of the TiO<sub>2</sub>/Pt/Au nanomotor with and without UV light irradiation. In the case of the without UV irradiation, the average speed of the nanomotor was 33 μm s<sup>-1</sup>. On the other hand, under UV irradiation, the speed of the nanomotor was 45 μm s<sup>-1</sup>, indicating that the speed of the nanomotor became faster by UV light irradiation. Light acceleration mechanism is suggested that decomposition of the hydrogen peroxide fuel on the TiO<sub>2</sub> surface. If no UV light was irradiated, hydrogen peroxide is oxidized only on the Pt surface, and the hydrated protons (H<sub>3</sub>O<sup>+</sup>) generated by hydrogen peroxide oxidation. The H<sub>3</sub>O<sup>+</sup> is moved toward to the Au side, and reduced on the Au surface. Thus, this nanomotor is driven by the water flow near nanomotor surface by self-electrophoresis [4]. If UV is irradiated, hydrogen peroxide is also oxidized on the TiO<sub>2</sub> surface by the photocatalytic reaction. Therefore, oxidation of H<sub>2</sub>O<sub>2</sub> is promoted, and then driving speed was found to increase.

*eugenijus.norkus@ftmc.lt*

The direct borohydride fuel cell is based on borohydride oxidation and oxygen electrochemical reduction, so the main attention is paid to the search of new nanostructured substances, which will be able to increase the efficiency of fuel cells as well as to use simple and cheap catalysts formation technologies.

In the present study investigation of sodium borohydride oxidation on cobalt-boron-copper and cobalt-boron-tungsten-copper modified with Au nanoparticles (denoted as Au/CoB/Cu and Au/CoBW/Cu) is presented. A series of the Au/CoB/Cu and Au/CoBW/Cu catalysts with low Au loadings were prepared by a simple way which involves electroless CoB and CoBW deposition followed by a spontaneous Au displacement from the gold-containing solution. The morphology and composition of the prepared catalysts were characterized using Field - Emission Scanning Electron Microscopy and Energy Dispersive X-ray Spectroscopy. The electrochemical behavior of the fabricated catalysts was examined towards the oxidation of  $\text{BH}_4^-$  ions in an alkaline medium by means of cyclic voltammetry and chrono-techniques.

It has been determined that the average size of Au crystallites deposited by galvanic displacement of CoB and CoBW adlayers varies from 6 up to 50 nm depending on the immersion time of CoB and CoBW/Cu electrodes into the gold-containing solution. The prepared Au/CoBW/Cu catalysts with the Au loadings in the range from 5.8 to 23.2  $\mu\text{g cm}^{-2}$  and Au/CoB/Cu with the Au loadings in the range from 8.0 to 44.2  $\mu\text{g cm}^{-2}$  demonstrated a significantly higher electrocatalytic activity towards the oxidation of  $\text{H}_2$  generated by catalytic hydrolysis of  $\text{BH}_4^-$  and the oxidation of  $\text{BH}_4^-$  ions as compared to those of bare Au, CoB/Cu or CoBW/Cu.

The prepared Au/CoB/Cu and Au/CoBW/Cu catalysts with low Au loadings seem to be a promising anodic material for direct borohydride fuel cells.

# Synthesis of Metal Nanoparticle/Graphene Nanocomposites using Atmospheric-Pressure-Microplasma-Assisted Electrochemistry

Huin-Ning Huang<sup>1</sup>, Wei-Hung Chiang<sup>1</sup>

[z22765820@gmail.com](mailto:z22765820@gmail.com)

Graphene represents a new type of carbon materials and have attracted lot of attention is due to its exceptional physical and chemical properties. Recently experimental and theoretical studies have been shown that the composites of metal nanoparticles (NPs)/graphene can process superior electrocatalytic property, making them promising candidates for fuel cell electrodes. However, conventional approach to synthesis metal NPs/graphene composites usually involve time-consuming and laborious wet-chemistry-based methods.

Here we present an facile synthesis metal NPs/graphene composites using a novel atmospheric-pressure microplasma-assisted electrochemistry. Microplasmas are defined as gaseous discharges formed in electrode geometries where at least one dimension is less than 1mm. Additionally, microplasmas can be operated with an aqueous solution as an electrode. Energetic species formed in the microplasma are capable of initiating electrochemical reactions and nucleating particles in solution without the need for a chemical reducing agent. In our experiments result, we found metal NPs can be synthesis in a minute time scale using atmospheric-pressure-microplasma-assisted electrochemistry, and we further extend this technology to synthesis metal NPs/graphene composites. As-produced samples were characterized by SEM , XRD , Raman and UV-Vis spectroscopy.

# The Use of Environmentally-Friendly Natural Polyols as Cu(II) Ligands in Electroless Copper Plating Processes

Eugenijus Norkus<sup>1</sup>, Janė Jačiauskienė<sup>1</sup>, Kęstutis Prušinskas<sup>1</sup>, Irena Stalnionienė<sup>1</sup>, Loreta Tamašauskaitė-Tamašiūnaitė<sup>1</sup>, Dordi Yezdi<sup>2</sup>, Aniruddha Joi<sup>2</sup>

<sup>1</sup>*Center for Physical Sciences and Technology, A. Goštauto 9, LT-01108 Vilnius, Lithuania*

<sup>2</sup>*Lam Research Corporation, 4650 Cushing Parkway, CA 94538 Fremont, U.S.A.*

*eugenijus.norkus@ftmc.lt*

The aim of the study presented herein was comparison of the parameters of process of electroless copper plating – mainly plating rate and nanoscale surface roughness of the copper deposits obtained, – using different polyols as copper(II) ligands under the similar conditions.

The ligands considered were glycerol, xylitol, *D*-mannitol, *D*-sorbitol and saccharose.

Cu(II) ligands are important components of common formaldehyde-containing alkaline electroless copper plating baths:

From one hand, the ligands used should form Cu(II) complexes stable enough to prevent Cu(OH)<sub>2</sub> formation, since the solubility product of Cu(OH)<sub>2</sub> is of the order 10<sup>-18</sup> and the concentration of “free” (uncomplexed) Cu(II) ions in the pH range 11–14 cannot exceed 10<sup>-12</sup>–10<sup>-18</sup> M, respectively. On the other hand, it is worth to note that kinetics of copper deposition as well as the properties of copper deposits (compactness, exterior, morphology and crystal structure) in high extent depend on the nature of ligands used for Cu(II) binding into complexes in electroless copper plating solutions.

The data on composition and stability of Cu(II) complexes with mentioned ligands also are presented and discussed.

## Different-sized truncated Pd nanocubes for glucose electrooxidization

Nan-Kuang Chou, Meng-Shan Hsieh, Chien-Liang Lee\*

*Department of Chemical and Materials Engineering, National Kaohsiung University of Applied Sciences*

*No. 415, Chien Kung Rd., Kaohsiung 807, Taiwan*

*e-mail address: [cl\\_lee@kuas.edu.tw](mailto:cl_lee@kuas.edu.tw); [cl\\_lee@url.com.tw](mailto:cl_lee@url.com.tw)*

Regular Pd nanocubes enclosed by (100) planes is of interesting for being as high-performance catalyst in non-enzymatic glucose sensor [1]. In this study, we symmetrically synthesized 22.8 nm and 34 nm truncated Pd nanocubes with eight (111) facets on corners and six (100) facets on planes and successfully used them as catalysts for glucose electrooxidation in 0.1 M NaOH solution. On the basis of the same Pd weight, the 22.8 nm Pd nanocubes showed  $0.044 \text{ cm}^2$  in electrochemical surface area (ESA), higher than  $0.037 \text{ cm}^2$  for the ESA of the 34 nm Pd nanocubes. The smaller Pd catalysts also have high anodic current in a reaction, in which glucose was oxidized to gluconolactone upon the promotion of Pd-OH. Additionally, the appearance of (111) planes induced two-ranged sensitivities when these two truncated Pd nanocubes were used in a non-enzymatic glucose sensor. Compared to larger Pd nanocubes, the smaller truncated Pd nanocubes had higher sensitivity, which were  $0.0618 \text{ mA mM}^{-1} \text{ cm}^{-2}$  within a linear range from 0.01 mM to 0.5 mM and  $0.0203 \text{ mA mM}^{-1} \text{ cm}^{-2}$  within a linear range from 1 mM to 15 mM for sensing glucose.

# Electrophoretic deposition of graphene sheets on porous nickel foam as effective catalysts for oxygen evolution reaction and hydrogen peroxide sensor

Yi-Shan Wu, Chien-Liang Lee\*

*Department of Chemical and Materials Engineering, National Kaohsiung University of Applied Sciences*

*No. 415, Chien Kung Rd., Kaohsiung 807, Taiwan*

*e-mail address: [cl\\_lee@kuas.edu.tw](mailto:cl_lee@kuas.edu.tw); [cl\\_lee@url.com.tw](mailto:cl_lee@url.com.tw)*

A method for the electrophoretic deposition of defective graphene sheets (DGSs) on porous Ni foams (DGS/Ni foam) is demonstrated. The comparative raman spectra showed that significant D band and G band on the DGS/Ni foam as compared to bare Ni foam, confirming the successful deposition of DGSs on the Ni foam. Additionally, the X-ray photoelectron spectra depicted the domination of C-OH and C=O on the surface of DGS/Ni foam. Additionally, the prepared DGS/Ni foam was successfully as high-performance catalysts for oxygen evolution reaction (OER) and hydrogen peroxide sensor. Compared to 1.67 V (vs. RHE) by conventional Pt/C catalyst, the DGS/Ni foam showed early onset potential started from 1.5 V (vs. RHE) and higher anodic current toward OER in a 0.1 M KOH electrolyte. In the application on hydrogen peroxide sensor, the DGS/Ni foam as compared with bare Ni foam showed larger current for reducing H<sub>2</sub>O<sub>2</sub> in the phosphate buffered saline solution. There were two linear current-responses relationships for the sensitivities on the DGS/Ni foam, which has 12.3  $\mu\text{A}\cdot\text{mM}^{-1}\cdot\text{cm}^{-2}$  from 1.6 mM to 7.6 mM and 4.7  $\mu\text{A}\cdot\text{mM}^{-1}\cdot\text{cm}^{-2}$  from 9.6 mM to 27.6 mM. The data in the selective tests depicted that DGS/Ni foam showed remarkable tolerance to foreign ascorbic acid and uric acid, confirming the potential of DGS/Ni foam as a H<sub>2</sub>O<sub>2</sub> sensor.

# Bacteria Derived Carbon as High-Performance Electrocatalysts

Yuan Chen

*School of Chemical and Biomedical Engineering, Nanyang Technological University, Singapore  
N1.2-B1-16, 62 Nanyang Drive, Singapore 637459  
chenyuan@ntu.edu.sg*

Nitrogen and phosphorus dual doped carbon materials have shown competing catalytic activity as metal-free catalysts for oxygen reduction reaction (ORR) and hydrogen-evolution reaction (HER). Prevailing methods to synthesize such carbon catalysts require high purity chemicals and gases, excessive amount of strong acids and bases, or costly organic precursors. Here, we show that bacteria can be used as a novel precursor to synthesize heterogeneous carbon materials with nitrogen and phosphorus dual functionalities by carbonization.

In the first case, *E. coli* cells were directly carbonized by heat treatment in Ar. The resulting carbon material has a large surface area up to 636 m<sup>2</sup>/g, and is comprised of up to 7.64 at% nitrogen and 8.53 at% phosphorus. The carbon material obtained at an optimum carbonization condition of 1000 °C for 2 h shows excellent catalytic performances, comparable to that of a 20 wt% Pt-C catalyst, with ~50% higher limiting current density, for ORR in near four-electron transfer processes and excellent durability. The outstanding electrocatalytic performances are credited to the fine tuning of nitrogen species by carbonization conditions and the synergy between nitrogen and phosphorus dual functionalities.<sup>1</sup>

In the second case, *S. aureus* cells were carbonized, resulting carbon material with a large surface area of 341 m<sup>2</sup>/g with nitrogen and phosphorus dual functionalities of 4.88 at% nitrogen and 4.23 at% phosphorus. Mesopores were further introduced by carbonization together with ZnCl<sub>2</sub> to increase the surface area to 816 m<sup>2</sup>/g. After cathodic treatment, the *S. aureus* derived carbon catalyst exhibits highly efficient electrocatalytic activity for the HER in acidic electrolytes. It demonstrates low onset overpotential of 76 mV, a Tafel slope of 58.4 mV/dec and a large normalized exchange current density of 1.72 × 10<sup>-2</sup> mA/cm<sup>2</sup>, which is comparable to or even better than that of existing metal-free and well-fabricated metallic catalysts. The excellent activity can be attributed to the synergistic effects of nitrogen and phosphorus, abundant mesopores, and structural and surface chemistry changes induced by the cathodic treatment.<sup>2</sup>

These two cases demonstrate the great potential of using bacteria to obtain carbon materials with a tailored structure and composition as electrocatalysts for sustainable chemical processes.

## Abstract

Here we report a controllable synthesis of Ag/GNRs composites using a two-step reaction route. First, we synthesized and functionalized GNRs from low to high by a facile carbon nanotube chemical unzipping. The functionalization of GNRs could be tuned by controlling reaction conditions (temperature, time, and oxidant concentration), confirming by scanning electron microscopy (SEM) and X-ray photoelectron spectroscopy (XPS) characterizations. (Fig. 1 and Fig. 2) Second, Ag NPs can be decorated onto the GNRs surface through a wet-chemical-based redox reaction. In our present experiment, we found that the loading of Ag NPs can be further controlled by controlling the reaction conditions. Detailed materials characterizations including SEM and UV-Vis spectroscopy (Fig. 2 and Fig. 3) show that Ag/GNRs composites were successfully synthesized in our experiment. And we also obtained Ag/GNRs substrate is extremely suitable for surface-enhanced Raman spectroscopy (SERS).

Figure1. SEM images of as-produced GNRs and Ag/GNRs with different (a, d) low surface functionality (L-GNRs and L-Ag/GNRs), (b, e) medium surface functionality (M-GNRs and M-Ag/GNRs) and (c, f) high surface functionality (H-GNRs and H-Ag/GNRs).

Figure2. XPS C1s spectra of as-produced GNRs

and Ag/GNRs with different (a, d) low surface functionality (L-GNRs and L-Ag/GNRs), (b, e) medium surface functionality (M-GNRs and M-Ag/GNRs) and (c, f) high surface functionality (H-GNRs and H-Ag/GNRs).

Figure3. UV-vis spectra of as-produced GNRs and Ag/GNRs with different (a) low surface functionality (L-GNRs and L-Ag/GNRs), (b) medium surface functionality (M-GNRs and M-Ag/GNRs) and (c) high surface functionality (H-GNRs and H-Ag/GNRs).

# Synthesis and Characterization of Highly Active Ir Nanoparticles for Oxygen Evolution Reaction in Acid Media

P. Lettenmeier, S. Hosseiny, L. Wang, A. S. Gago, K. A. Friedrich

*Institute of Engineering Thermodynamics, German Aerospace Center  
Pfaffenwaldring 38-40, 70569 Stuttgart, Germany*

*Philipp.lettenmeier@dlr.de*

Proton exchange membrane (PEM) water electrolysis is one of the most promising technologies for a sustainable and emission-free hydrogen production due to its high power density and high efficiency [1]. High amounts of expensive noble metals, such as platinum and iridium for cathode and anode side respectively, contribute significantly to the high investment cost of the stack [2]. Therefore, lower loadings of platinum group metals can reduce significantly the overall cost of PEM electrolysis. In this work we synthesise nano-sized iridium particles by reducing  $\text{IrCl}_3$  in anhydrous  $\text{C}_2\text{H}_6\text{O}$  at room temperature. Transmission electron microscopy (TEM) images show Ir clusters with a uniform particle size distribution (Figure 1a). X-ray diffraction (XRD) analysis reveals a cubic face centred structure of the Ir nanoparticles with a crystallite size of approx. 1.8 nm. X-ray photoelectron spectroscopy (XPS) confirms the metallic properties of the Ir particles covered with a very thin oxide layer. Atomic force microscopy (AFM) measurements show that a catalyst layer containing the Ir nanoparticles and Nafion ionomer has a non-uniform surface electrical conductivity. Rotating disc electrode (RDE) investigations such as cyclic and linear voltammetry are performed and the results compared with commercial Ir black. The synthesized catalyst shows a nine-fold higher activity towards oxygen evolution reaction (OER) than Ir black at 0.25 V overpotential and 25°C. This result is in good agreement with the CO-stripping measurements (Figure 1b) from which  $6.9 \times 10^{-4}$  and  $4.4 \times 10^{-4} \text{ mol}_{\text{CO}} \text{ gr}_{\text{Ir}}^{-1}$  active sites are determined for Ir nanoparticles and Ir black, respectively. The effect of thermal treatment and electrochemical performance of the catalysts in the PEM electrolyser are discussed as well.

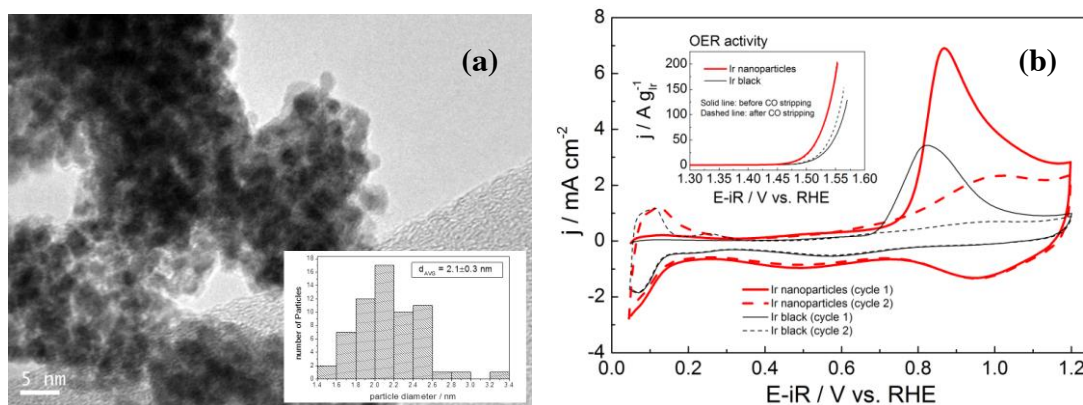

Fig. 1. (a) TEM image with particle size distribution of Ir nanoparticles and (b) CO-stripping in comparison with commercial Ir black. The measurements were carried out at a scan rate of  $50 \text{ mV s}^{-1}$ , in Ar-saturated 0.5 M  $\text{H}_2\text{SO}_4$  electrolyte. The inset of (b) shows the corresponding mass activity characteristics for OER measured at  $5 \text{ mV s}^{-1}$ . The rotation speed of the electrode is 2500 rpm.

# Assembly of hybrids based on Keggin POMs and Co-tris(imidazolyl) complexes with bifunctional electrocatalytic activities

Wanli Zhou,<sup>ab</sup> Jun Peng,<sup>\*a</sup>

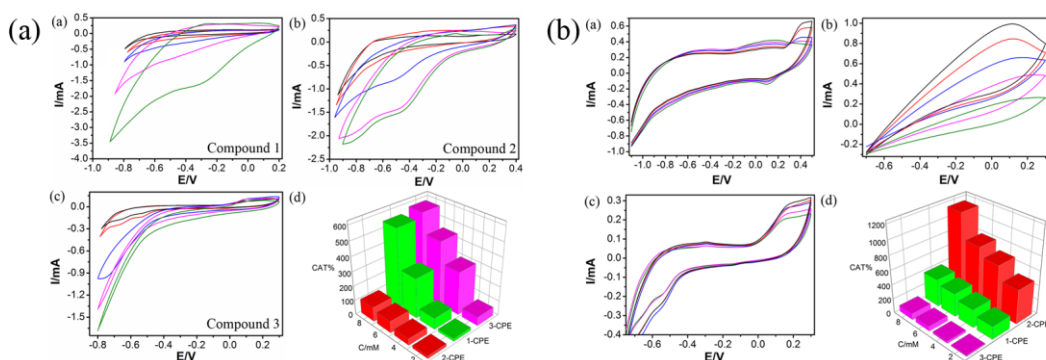

<sup>a</sup> Key Laboratory of Polyoxometalate Science of Ministry of Education, Faculty of Chemistry, Northeast Normal University

Changchun, Jilin, 130024, PR China

<sup>b</sup> Faculty of Chemistry, Tonghua Normal University

Tonghua, Jilin, 134002, PR China

E-mail: jpeng@nenu.edu.cn

Three new organic-inorganic hybrid compounds based on the Keggin POMs and Co-tib motifs were hydrothermally synthesized by utilizing a pH-dependent approach in the same POM/Co/tib reaction systems. The electrocatalytic properties of compounds **1-3** were studied by cyclic voltammetry, and compounds **1-3** displayed bifunctional electrocatalytic activities toward reduction of nitrite and oxidation of ascorbic acid (AA). The electrocatalytic efficiencies of n-CPE are in an order of **3-CPE** > **1-CPE** > **2-CPE** for nitrite reduction, and **2-CPE** > **1-CPE** > **3-CPE** for AA oxidation. These results indicate that Keggin  $\alpha$ -BW<sub>12</sub> hybrids exhibit better performances than that for Keggin  $\alpha$ -SiW<sub>12</sub> hybrid towards electrocatalytic reduction of NO<sub>2</sub><sup>-</sup>, and conversely, Keggin  $\alpha$ -SiW<sub>12</sub> hybrid exhibits a better performance towards electrocatalytic oxidations of AA than those for Keggin  $\alpha$ -BW<sub>12</sub> hybrids. The differences of electrocatalytic performances between the two series of Keggin POM hybrids and among  $\alpha$ -BW<sub>12</sub> hybrids are perhaps due to the differences in their structures and electrochemical properties.

We thank the National Natural Science Foundation of China (Grant 21373044) for financial supports.

# SUCCESSFUL STRATEGIES TO OVERCOME THE CARBON ELECTRODE SURFACES FOULING OF PHENOLS

Abdel-Nasser Kawde  
*Chemistry Department, King Fahd University of Petroleum and Minerals,  
Dhahran, 31261, Saudi Arabia  
akawde@kfupm.edu.sa*

The first strategy to overcome the well-known carbon electrodes surface fouling of phenols is about a simple and rapid method for the preparation of a disposable porous Cu-modified graphite pencil electrode (Cu-GPE) for sensing 4-nitrophenol (4-NP). The bare and Cu-modified graphite pencil electrodes were characterized by cyclic voltammetry and SEM. The two electrodes displayed distinct electrocatalytic activities in response to the electrochemical redox reaction of 4-NP. A difference of three orders of magnitude is obtained in the amperometric detection limits of 1.9 mM on porous Cu-modified vs. 1.0 mM on bare-graphite pencil electrode at 3s. The Cu-GPEs are fabricated utilizing a simple single method, and at an extremely low cost with high stability, selectivity, and sensitivity, offering a promising tool for sensing 4-NP.

The second strategy was developed for phenol and chlorophenols, and conducted on the surface of glassy carbon by cyclic and square-wave stripping voltammetry, and by Fourier-transform infrared spectroscopy. The surface fouling is accompanied by the appearance of reversible peaks at lower potential range (+0.1 to +0.4 V), which grew up with CV cycling and attributed to the electro-redox reactions of formed polymer film via electropolymerization. The electroanalytical monitoring of formed polymer oxidation peaks improved both sensitivity and detection limit by thirty-five and ten times, respectively. The FT-IR supported semiempirical prediction attributed the electropolymerization to the formation of ortho-para and/or ortho-meta C-C coupled-system.

# Electrodeposition of Nanoflake Pd Structures: Structure-Dependent Wettability and SERS Activity

Hwakyeung Jeong, Jongwon Kim\*

Department of Chemistry, Chungbuk National University  
Cheongju, Chungbuk 361-763, Korea  
hkborn@naver.com

The nanostructured metal surfaces have unique physical and chemical properties different from bulk state, and then such metal surfaces provide various applications. Specific properties of nanostructured metal surfaces can be controlled by their shape and size. Therefore, the fabrication of well-defined nanostructured metal surfaces has been the subject of intensive research. The electrodeposition methods with simplicity in fabrication route provide clean nanostructured metal surfaces. In this work, a one-step electrodeposition of nanoflake Pd structures onto clean Au surfaces without the use of additives was reported. The fine structure of the nanoflake Pd surfaces was regulated by controlling the deposition charge. The wetting property and surface-enhanced Raman scattering (SERS) activity among the characteristic properties of nanostructured metal surfaces have been received great attention. The wettability of solid surfaces is important in many technological fields, such as fabrication of self-cleaning materials, manipulation of biomaterials, and microfluidics. And the SERS techniques provide useful applications, such as biological sensing and trace analysis. In present work, the effect of the structural variations on the wettability and SERS activity was examined. The wettability of nanoflake Pd structures was closely related to the fine structures of Pd deposits and their surface roughness. The SERS activity of the nanoflake Pd surfaces was dependent on the sharp edge sites on the Pd structures. Nanoflake Pd structures with deposition charge of 0.04 C exhibited superhydrophobic natures and reproducible SERS activity. The effect of the metal surface structures on the wettability and the SERS activity provides insight into the fabrication of functional metal nanostructures.

In this study, Cu nanoparticles (Cu NPs) were prepared by controlled-potential bulk electrolysis at -2.0 V and dispersed in tributylmethylammonium bis((trifluoromethyl)sulfonyl)imide room-temperature ionic liquid (Bu<sub>3</sub>MeN-TFSI RTIL)<sup>1</sup>; the chemical structure of RTIL are shown in Fig 1. The Cu(I) species were introduced into the RTIL by anodic dissolution of a Cu metal wire. The Cu NPs shown in Fig 2 were characterized with transmission electron microscope (TEM) and scanning electron microscope (SEM). Then Cu NPs-IL were mixed with the graphite powder and spread onto the screen-printed carbon electrode (SPCE) to form the IL-graphite-CuNPs composite electrode (IL-GP-Cu NPs). The electrochemical behavior of IL-GP-Cu NPs were investigated in 1 M NaOH by cyclic voltammetry (CV), however, the stability of IL-GP-Cu NPs was not good enough and further experiments are still needed.

# Synthesis of Excavated Trioctahedral Au–Pd Alloy Nanocrystals with Tunable Composition for Electro-Oxidation of Ethanol

Qiaoli Chen, Zhaoxiong Xie\*

State Key Laboratory of Physical Chemistry of Solid Surfaces, Collaborative Innovation Center of Chemistry for Energy Materials, and Department of Chemistry, College of Chemistry and Chemical Engineering

Xiamen University, Xiamen 361005 (China)

E-mail: zxxie@xmu.edu.cn

Direct ethanol fuel cells (DEFCs) have received a great interest and attention due to its high energy density and easy storage and transport. Besides, ethanol is clean energy that can be produced from a wide range of sources.[1] But the mechanism of the electro-oxidation of ethanol is much complicated because it should cleave C–C bonds and refers to the transfer of 12 electrons.[2] What's more,  $\text{CH}_3\text{COOH}$  and  $\text{CH}_3\text{CHO}$  are always dominant in the final products. Ethanol is difficult to be oxidized on Pt-based electrocatalysts. In order to replace for platinum and pursue for fast kinetic and high stability, Pd-based nanocrystals are emerging as an attractive electrocatalysts in DEFCs, which are more active towards electro-oxidation of ethanol in alkaline media than in acidic media.[3] On the other hand, the catalytic activity is highly depended on the surface structure and composition of catalysts.[4] The excavated structures gather the features of high specific area and well-defined facets, which would lead to absolutely improvement on electrocatalytic performances. [5]

Herein, we report the synthesis of excavated trioctahedral Au–Pd alloy nanocrystals with tunable composition. It is also demonstrated that the as-prepared Au–Pd alloy nanocrystals exhibit higher electrocatalytic activity towards ethanol oxidation than Pd black. Figure 1 shows the characterization of the as-prepared Au–Pd alloys nanocrystals.

Transglutaminase (tTG), a calcium dependent enzyme catalysis protein cross linkages such as glutamine to the lysine on proteins. Transglutaminase exhibits high specificity towards glutamine substrates and forms an enzyme complex with gliadin that produces an immune response against this complex [1-2]. This immune response resulted in the identification of transglutaminase as the auto antigen of celiac disease. Since transglutaminase is predominantly involved in the activation and progression of celiac disease, it results in the production of antibodies against it. This then results in the harmful damage to the small intestine which reduces food digestion diffusion into the blood vessels [3]. The standard diagnosis of celiac disease is tedious and expensive. The diagnosis of coeliac disease can be done by the measurement of antibodies against transglutaminase [4]. In this work, an electrochemical impedimetric immunosensor was developed for the detection of anti-transglutaminase antibodies. The immunosensor consisted of a polypyrrole-cobalt (II) salicyladiimine metallodendrimer composite on a platinum electrode with transglutaminase as the recognition element. Atomic force microscopy was used to determine surface roughness of the modified platinum electrode with values of 879.24 nm, 76.55 nm and 364.27 nm for polypyrrole, cobalt (II) salicyladiimine and their respective composite. The composite provided a suitable micro-environment for monitoring antibody-antigen interactions in conjunction with their cyclic voltammetry. Electrochemical impedance spectroscopy parameters such as exchange current and heterogeneous rate constant are used to evaluate immunosensor where the rate constants were  $2.7 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ ,  $4.6 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$  and  $4.16 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$  for cobalt (II) salicyladiimine metallodendrimer, polypyrrole and their composite. Impedimetric detection of anti-transglutaminase antibody gave a limit of detection of 201 ng/mL and linear range of  $10^{-5}$  -  $10^{-4}$  mg/mL with correlation coefficient of 0.948.

Figure 1. Nyquist plot for anti-tTG antibody incubation at, (a)  $2.85 \times 10^{-4}$  mg/mL, (b)  $5.7 \times 10^{-4}$  mg/mL, (c)  $8.55 \times 10^{-4}$  mg/mL, (d)  $11.4 \times 10^{-4}$  mg/mL, (e)  $14.25 \times 10^{-4}$  mg/mL, (f)  $17.1 \times 10^{-4}$  mg/mL and calibration graph for immunosensor  $R_{ct}$  versus anti-tTG antibody concentration in 0.1 M phosphate buffer. B) Calibration plot for the detection of anti-tTG antibody in 0.1 phosphate buffer.

# Enhancement on ORR activity of N-doped carbon catalysts derived from melamine based polymer

Dong Wook Lee, Woong Hee Lee, Hansung Kim\*

Dept. of Chemical and Biomolecular Engineering, Yonsei University  
50 Yonsei-ro, Seodaemun-gu, 120-479, Seoul, Korea

\*e-mail: [elchem@yonsei.ac.kr](mailto:elchem@yonsei.ac.kr)

The study of the oxygen reduction reaction (ORR) is an important issue in fuel cell. Generally, Pt-based catalysts are used as the electrical catalyst for the ORR [1]. However, because of the high cost and limited supply of Pt, substantial research efforts have been devoted recently to develop a highly active non-noble catalyst for the ORR to replace Pt. Alternative materials such as metal oxides [2], transition metal chalcogenides [3], nitrogen-doped carbons [4] have been reported as non-precious ORR catalysts. Among them, nitrogen-doped carbons are highly favoured as non-precious metal catalysts for the ORR because of their relatively high activity and stability. Recently, melamine ( $C_3H_6N_6$ ), which is an industrial material with three triazine heterocyclic organic compound, has been extensively examined as a nitrogen precursor in the preparation of nitrogen-doped carbon catalysts because of its low-cost and high nitrogen content [5]. Various works using melamine were conducted previously. However, they were mostly used in the form of monomer.

In this study, we investigated the ORR activity of nitrogen-doped carbon catalysts that were prepared by pyrolyzing melamine-based polymer-coated carbon black and compared it with that prepared using melamine monomer as a nitrogen precursor. Additionally, we also examined the synergic effect of presence of cobalt. The linear sweep voltammogram that was conducted in an alkaline solution shows that the ORR activity of the nitrogen-doped carbon catalysts increases significantly close to that of Pt/C when a polymerized melamine is used as a nitrogen precursor instead of a melamine monomer. From the XPS-N 1s analysis, the introduction of the melamine-based polymer positively contributes to the nitrogen doping content and formation of a graphitic-N and pyridinic-N, which is known to be an active site for the ORR. Therefore, based on the quantitative analysis of the experimental results, melamine-based polymer is a promising precursor of nitrogen-doped carbon catalysts for ORR catalysts.

# Structure vs. Properties Relation in Novel RuPt Core-Edge Catalyst Nanoclusters

S. R. Brankovic<sup>1,2</sup>, Q. Yuan<sup>1</sup>, H. A. Doan<sup>2</sup> and Lars Grabow<sup>2</sup>

1) Electrical and Computer Engineering Department

2) Chemical and Biomolecular Engineering Department

University of Houston, Houston TX 77204-4005

SRBrankovic@uh.edu

Using a two-step process consisting of underpotential deposition techniques and surface limited red-ox replacement a novel so called “2D core-edge” monolayer catalyst morphology was synthesized. The core-edge nanoclusters are deposited on Au(111) and are composed of a Ru core surrounded by a Pt edge, RuPt<sub>ML-CE</sub>/Au(111). STM analysis confirms that the synthesized 2D core-edge nanoclusters are of monoatomic height and CV experiments confirm their superior CO electro-oxidation activity that exceeds the activity of Ru<sub>ML</sub>/Au(111) and Pt<sub>ML</sub>/Au(111) by nearly an order of magnitude. The unique catalytic activity of the RuPt<sub>ML-CE</sub>/Au(111) catalyst is explained in terms of its rich adsorption energy landscape, which is a direct result of the surface reconstruction of the Ru core to form concentric ripples, Figure 1 [1]. The characteristics of the adsorption energy landscape of the rippled core-edge structure were determined by a combination of DFT calculations and SNFTIRS experiments and point towards thermodynamically favorable radial transport from the Ru core to the active Ru-Pt interface. The diffusion of OH in the radial direction is slow, while CO is relatively mobile. Based on the experimental and computational data we propose a mechanism in which immobile OH species prevent CO diffusion and cause a transport controlled current plateau in the CV graph at low potentials. At higher potentials the Ru core region becomes active for CO oxidation leading to temporary removal of OH. This allows rapid diffusion of CO in the Ru core region to the Ru-Pt interface, where it can rapidly react. We postulate that the investigated RuPt<sub>ML-CE</sub>/Au(111) catalyst has

(electrochemical) applications beyond CO oxidation, e.g. methanol oxidation, and that analogous core-edge structures with different metal components can be synthesized. Our synthesis technique for the preparation of this novel 2D morphology opens up a new and entirely unexplored design space for monolayer catalysts, specifically if a reaction can benefit from bi-functional catalytic behavior.

**Figure 1.** Half-cut of the RuPt core-edge nanocluster with cross-section showing the rippled morphology and displacement of the atoms with respect to underlying Au substrate.

# Improved Visible-light Photoelectrochemical Water Oxidation using Titanium Dioxide /Antimony Trisulfide Heterojunction Structure

Yung-Tao Sung, Jun-Ming Chiu, Chao-Chi Tu, Lu-Yin Lin

Department of Chemical Engineering and Biotechnology, National Taipei University of Technology, 1 Sec. 3, Zhongxiao E. Rd., Taipei 10608, Taiwan, R.O.C., E-mail (L. Y. Lin\*): [lylin@ntut.edu.tw](mailto:lylin@ntut.edu.tw)

Since Fujishima and Honda have reported on the photoelectrolysis of water into hydrogen and oxygen on a  $\text{TiO}_2$  photoelectrode,<sup>1</sup> the semiconductor-based device for water splitting by solar energy has become one of the most important ways for oxygen generation.<sup>2</sup> Generally,  $\text{TiO}_2$  is one of the ideal candidates for its low cost, good photocatalytic activity, and chemical stability.<sup>3</sup> However, due to the large band gap ( $\sim 3.2$  eV),  $\text{TiO}_2$  can only harvest the ultraviolet (UV) light which takes only 5% of sunlight, resulting in low energy conversion efficiency.<sup>4</sup> Nonetheless, antimony trisulfide ( $\text{Sb}_2\text{S}_3$ ) has a smaller band gap ( $\sim 1.65$  eV) and band positions of  $-3.75$  and  $-5.4$  eV respectively for the conduction band and the valence band,<sup>5</sup> which is a suitable coating material for  $\text{TiO}_2$  nanorod array to perform oxygen generation. In this study,  $\text{Sb}_2\text{S}_3$  has been successfully synthesized by a chemical bath deposition method and coated onto the  $\text{TiO}_2$  nanorod arrays to form a heterojunction structure for obtaining higher photocurrent density. **Figure 1** is the scanning electron microscope (SEM) image of  $\text{TiO}_2$  nanorod array. The diameter and length of the nanorods are estimated to be  $0.1\ \mu\text{m}$  and  $2\ \mu\text{m}$ , respectively. The UV-visible spectroscopic measurement was carried out to the absorption of the samples as shown in **Figure 2**. It is observed that the  $\text{TiO}_2$  nanorod array hardly harvests light above  $400\ \text{nm}$ . On the contrary, the heterojunction structure shows an enhanced absorbance for the wavelength in the range of  $400$  to  $550\ \text{nm}$ . Finally, the photoelectrochemical performances of the electrode with  $\text{TiO}_2$  and  $\text{TiO}_2/\text{Sb}_2\text{S}_3$  heterojunction structures were measured by using a linear sweep voltammetry (LSV) plots as presented in **Figure 3**. An enhanced photocurrent density of  $0.32\ \text{mA}/\text{cm}^2$  at  $1.23\ \text{V}$  vs. RHE was obtained, which is higher than that of the electrode with bare  $\text{TiO}_2$  nanorod array. The better performance for the case with  $\text{TiO}_2/\text{Sb}_2\text{S}_3$  heterojunction structures is due to the enhanced visible light absorption and better electron migration resulting from the heterojunction property.

**Fig. 1** The SEM image of the top-view for  $\text{TiO}_2$  nanorod array, and the side-view image is also inserted in this figure.

**Fig. 2** Absorption spectra of pristine  $\text{TiO}_2$  nanorod and  $\text{TiO}_2/\text{Sb}_2\text{S}_3$ .

**Fig. 3** LSV plots of pristine  $\text{TiO}_2$  nanorod and  $\text{TiO}_2/\text{Sb}_2\text{S}_3$ .

# Kinetic Isotope Effect on Hydrogen Evolution and Oxidation Reaction

Hisayoshi Matsushima, Shota Shibuya, Ryota Ogawa, Mikito Ueda  
Faculty of Engineering, Hokkaido University,  
Kita 13 Nishi 8, Sapporo, Hokkaido 060-8628, Japan  
matsushima@eng.hokudai.ac.jp

Water electrolysis has been studied for deuterium separation for long time. The advantage is the high separation factor. The effective separation mechanism is attributed to the kinetic factors for hydrogen evolution reaction (HER). Nowadays, many researchers have actively investigated the Tafel slope and the exchange current of a polycrystalline platinum electrode, while the kinetic studies of deuterium evolution reaction (DER) are hardly measured experimentally [1]. Concerning on hydrogen oxidation reaction (HOR) which is the reverse reaction of HER, the comprehensive investigation is still under discussion [2]. Moreover, the fundamental kinetic data of deuterium oxidation reaction (DOR) have not been measured at all. We have proposed the new separation system combined with PEM fuel cell [3] and investigated the electrochemical kinetic factors of the hydrogen electrode reactions in both acid and alkaline aqueous solutions.

The working electrode was a  $0.785 \text{ cm}^2$  polycrystalline Pt disk and the counter one was coiled Pt wire. The reference electrode was Hg/Hg<sub>2</sub>SO<sub>4</sub> saturated with K<sub>2</sub>SO<sub>4</sub>. The rotating disc electrode with the rotation rate of 900, 1600, 2500 and 3600 rpm was used. The polarization curves were recorded by linear sweep voltammetry at the scan rate of  $\pm 0.01 \text{ V s}^{-1}$ .

Figure 1 shows the polarization curves for (a) HER/HOR in 0.05 M H<sub>2</sub>SO<sub>4</sub> and (b) DER/DOR in 0.05 M D<sub>2</sub>SO<sub>4</sub> electrolyte. Before the electrochemical measurements, open circuit potentials (OCP) were -0.725 V in H<sub>2</sub>SO<sub>4</sub> and -0.730 V in D<sub>2</sub>SO<sub>4</sub> electrolyte, respectively. The evolution reaction currents were independent of the rotation rate in both electrolytes, while the oxidation ones were significantly influenced by the forced convection at more than (a) -0.65 V and (b) -0.70 V, respectively. The limiting current densities, which were induced by the diffusional limitation of the dissolved hydrogen gas, appeared at high electrode potential ( $E > -0.5 \text{ V}$ ). The separation factors during hydrogen evolution and oxidation reaction will be reported.

# Fabrication of nanostructured copper phosphate electrodes for the detection of $\alpha$ -amino acids

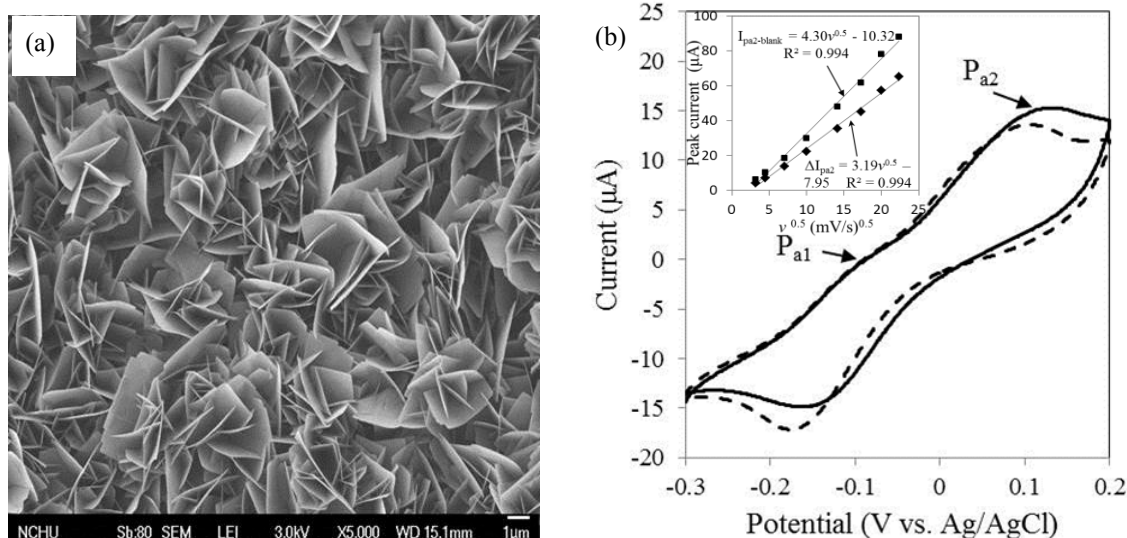

Ching-Chou Wu, Ming-Yuan Lee

Department of Bio-industrial Mechatronics Engineering, National Chung Hsing University

No. 250 Kuo-Kuang Rd. Taichung, Taiwan 402

ccwu@dragon.nchu.edu.tw

Increased attention has recently focused on the fabrication of different nanostructured copper compounds due to their unique surface-enhanced photocatalytic and electrocatalytic [1] characteristics.  $\text{Cu}_3(\text{PO}_4)_2$ -deposited electrodes capable of detecting nonelectroactive  $\alpha$ -amino acids (AAs) are developed by the dissolution-precipitation method. The  $\text{Cu}_3(\text{PO}_4)_2$ -dominated compounds of flake-shaped nanostructures, as shown in Fig. 1(a), can be quickly and uniformly deposited on the surface of acicula-nanostructured  $\text{Cu}(\text{OH})_2$ -electrodeposited electrodes in a 100 mM  $\text{Na}_2\text{HPO}_4$  solution (pH 5.0) within 2 h. Analysis of X-ray photoelectron spectroscopy and electrochemical kinetics shows an oxidative reaction at +0.11 V can increase the ratio of  $\text{H}_2\text{PO}_4^{1-}$  on the electrode surface and produce the  $\text{Cu}^{\text{II}}(\text{H}_2\text{PO}_4)_2$  complex. Moreover, the  $\text{Cu}^{\text{II}}$  compounds and the AAs can form complexes to accompany the chemical oxidation of AAs and the formation of the  $\text{Cu}^{\text{I}}$  complex, increasing the amount of oxidative current detected via the chemical-electrochemical mechanism. Figure 1(b) takes cysteine (Cys) as an example to show the electrocatalytic property of the  $\text{Cu}_3(\text{PO}_4)_2$  electrodes, presenting a diffusion-controlled behavior. The amperometric response presented good linearity and sensitivity in the range of 143–600  $\mu\text{M}$  for electroactive and nonelectroactive  $\alpha$ -AAs. The  $\text{Cu}_3(\text{PO}_4)_2$ -deposited electrode has potential as an AA sensor for integration into separation systems such as high performance liquid chromatography for use in biomedical diagnostics and food industry applications [2].

**Fig. 1** (a) SEM morphological images of the  $\text{Cu}(\text{OH})_2$ -deposited electrodes after being dipped for 2 h in 100 mM  $\text{Na}_2\text{HPO}_4$  solutions of 5.0 for 2 h. (b) The cyclic voltammograms (CVs) measured in blank (dashed line) and 1mM Cys-containing (solid line) 20 mM  $\text{Na}_2\text{HPO}_4$  (pH 5.0) with a 20 mV/s scanning rate. Inset shows the  $I_{Pa2-blank}$  and  $\Delta I_{Pa2}$  versus the square root of scan rate ( $v$ ).

# A poly(benzoxazine) as binder matrix for OER catalysts derived from Prussian blue analogue precursors

Stefan Barwe, Stefan Klink, Wolfgang Schuhmann

Analytical Chemistry – Center for Electrochemical Science (CES), Ruhr-Universität Bochum,  
Universitätsstr. 150, 44780 Bochum, Germany  
stefan.barwe@rub.de

Electrocatalysis is facing two major issues next to the development of low-cost and non-precious metal catalysts; catalysts have to be immobilized on an electrode surface in a stable manner and non-conductive catalysts necessitate the addition of conducting additives. In our work we introduce poly(benzoxazine) (pBO) resins as a new class of binder material into the field of electrocatalysis. pBOs consist of highly crosslinked networks of benzoxazine monomers or oligomers, whereas benzoxazines (BO) are heterocyclic compounds comprising an oxazine ring connected to a benzene ring. They arise from Mannich type reactions of primary amines, aldehydes and phenol derivatives. The complexity due to the large variety of starting materials leads to a nearly endless diversity in possible new benzoxazine resins with properties such as (i) near-zero shrinkage during polymerization, (ii) little water absorption, (iii)  $T_g$  higher than other thermosets, (iv) no need of strong acids and bases as catalysts, (v) economical and commercial available starting materials and (vi) no side-products after polymerization.<sup>1</sup>

Thermal polymerization of a mixed film of a bisphenol A and aniline based BO monomer and a Prussian blue analogue (PBA) drop-casted on an electrode surface led to a polymer layer with incorporated PBA particles (Figure 1). Pyrolysis transformed the deposited pBO/PBA film into a conducting carbon matrix doped with metal oxides (Figure 1). The metal oxide composition is determined by the PBA precursor used for drop-casting, various stoichiometries of Ni, Co, Mn and Fe are possible. Scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDX) verify the composition and appearance of the resulting metal oxide particles. Moreover, the cubic structure of a manganese hexacyanocobaltate precursor is not affected by the pyrolysis and inclusion into the carbon matrix. The produced C/PBA composites show a significant activity towards the OER (while a pure pBO based carbon matrix shows no activity), furthermore is it exceeding the activity of the pyrolysis product of the same PBA immobilized in a Nafion layer. Consecutive cyclic voltammograms exhibit a rising catalytic activity with each cycle. This increase in activity is evoked by the detachment of carbon matrix, releasing more and more active sites of the catalyst. Galvanostatic measurements promote the catalyst activation and reveal a stability of at least 14 h. Hence, we were able to generate OER active catalysts, based on transition metal oxides, embedded into a conducting carbon matrix with a good stability via pyrolysis of a two-component system directly on an electrode surface, obviating the need of additional binder or conducting additives.

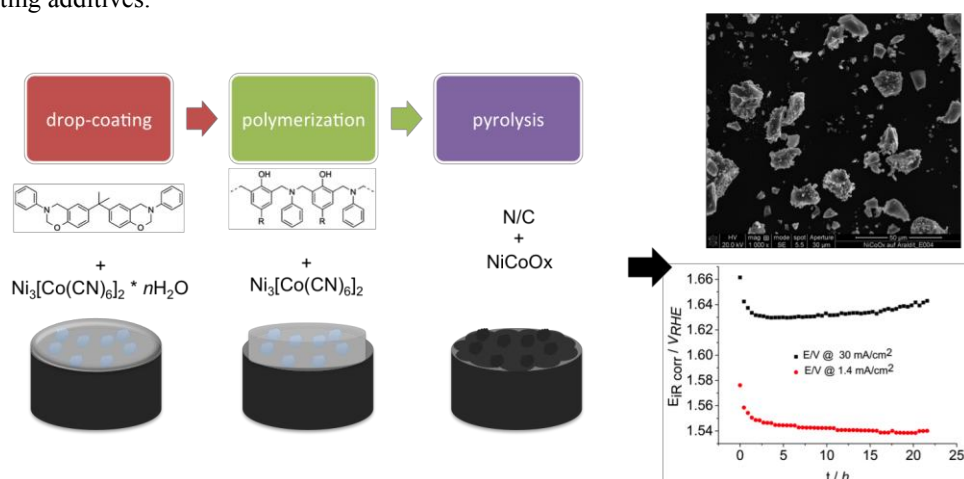

Figure 1: Schematic representation of the electrode preparation; SEM picture of  $\text{NiCoOx}$  particles; measured potential change at two different current densities (black squares: potential at 30  $\text{mA}/\text{cm}^2$ ; red circles: potential at 1.4  $\text{mA}/\text{cm}^2$ ).

# Three-dimensional Nickel Film Electrodeposited on Porous Carbon Sponge: High Catalytic Performance and Low-cost Anode for Urea Electro-oxidation in Alkaline Medium

Ke Ye<sup>\*</sup>, Dianxue Cao, Hongyu Zhang, Long Yang, Xin Wang, Kui Cheng

Key Laboratory of Superlight Materials and Surface Technology, Ministry of Education, College of Materials Science and Chemical Engineering, Harbin Engineering University, Harbin, 150001, P.R. China.

e-mail address: yeke@hrbeu.edu.cn

In order to satisfy the increasing global demands for energy, alternative clean energy sources independent of fossil fuels, must be developed. Urine is the most abundant waste on the earth. The largest constituent of human or animal urine is urea ( $\text{CO}(\text{NH}_2)_2$ ), which is a significant organic source of H, C, O, and N. In addition, a large amount of wastewater with different concentrations of urea is produced during the industrial synthesis of urea, suggesting the availability of a considerable amount of urea in municipal wastewater. Thus, urea rich wastewater has been identified as a source for sewage disposal, hydrogen production and fuel cells [1]. Direct urea fuel cell (DUFC) is composed of urea in alkaline electrolyte as the fuel and humidified oxygen as the oxidant. The theoretical open circuit voltage of DUFC is 1.147 V, which is comparable with that of  $\text{H}_2\text{--O}_2$  fuel cell (1.23 V). Highly efficient electrocatalysts play key roles for improvements of the DUFC performance [2]. Nickel is an ideal non-noble metal anode catalyst for DUFC due to its high activity with low cost, but the planar and flat nickel electrode had a defect that the onset oxidation potential of urea reached higher than 0.35 V (vs. Ag/AgCl), which would reduce the open circuit voltage of DUFC. Therefore, facile and reasonable design and fabrication of three-dimensional (3D) structures is imperative for high electrocatalytic activity towards urea electro-oxidation in alkaline medium. Highly porous 3D structures are one of the optimal candidates due to the superior porosity and high specific surface area which can afford easy transport pathways for both electrons and ions.

Herein, we report the Ni electrocatalysts directly deposited on the porous carbon sponge with high electrocatalytic performance for urea electro-oxidation in alkaline medium. Highly porous nickel@carbon sponge electrode with low cost is synthesized via a facile sponge carbonization method coupled with a direct potentiostatic electrodeposition of Ni on the surface of carbon sponge at a constant potential of  $-1.0$  V (vs. Ag/AgCl) for 4200 s (Fig. 1). The obtained electrodes are characterized by X-ray diffraction (XRD), scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDX). The catalytic performances of urea electro-oxidation in alkaline medium are investigated by cyclic voltammetry (CV) and chronoamperometry (CA). The Ni@carbon sponge electrode exhibits three-dimensional open network structures with a large surface area. Remarkably, the Ni@carbon sponge electrode shows much higher electrocatalytic activity and lower onset oxidation potential towards urea electro-oxidation compared to a Ni/Ti flat electrode synthesized by the same procedure. The Ni@carbon sponge electrode achieves an onset oxidation potential of 0.24 V (vs. Ag/AgCl) and a peak current density of  $290 \text{ mA cm}^{-2}$  in  $5 \text{ mol L}^{-1}$  NaOH and  $0.10 \text{ mol L}^{-1}$  urea solutions accompanied with a desirable stability. The impressive electrocatalytic activity is largely attributed to the high intrinsic electronic conductivity, superior porous network structures and rich surface Ni active species, which can largely boost the interfacial electroactive sites and charge transfer rates for urea electro-oxidation in alkaline medium, indicating promising applications in fuel cells.

## Introduction

Organic chemical hydride system, especially toluene (TL) / methylcyclohexane (MCH) system, is one of the most efficient systems for hydrogen storage and transportation. We have focused on a direct hydrogenation electrolyzer to improve energy conversion efficiency of the TL / MCH system. In the electrolyzer, cathode and anode reactions are hydrogenation of TL and oxygen evolution reaction (OER), respectively. TL that crosses over from cathode to through electrolyte membrane would adsorb onto the anode surface. It causes the overpotential increase and the degradation acceleration [1]. IrO<sub>2</sub> based electrocatalyst-coated electrode often used for OER in acidic medium, and adding tantalum to IrO<sub>2</sub> based catalyst inhibits the overpotential increase by organic contamination [1]. However, degradation of IrO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> / Ti electrode with TL contamination had never reported enough.

In this study, we have studied the relationship between annealing temperature for IrO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> / Ti electrode and degradation of the anodes to improve high durability.

## Experimental

A working electrode was a Ti plate coated IrO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> by thermal decomposition at 500 or 700°C. The degradation was investigated under constant current electrolysis at 400 mA cm<sup>-2</sup> in 1 M (= mol dm<sup>-3</sup>) H<sub>2</sub>SO<sub>4</sub> with saturated TL and benzyl alcohol at 60°C in a 2-electrode electrochemical cell. During electrolysis, polarization and catalyst loading were determined by a 3-electrode electrochemical cell in 1 M H<sub>2</sub>SO<sub>4</sub> with or without saturated TL and X-ray fluorescence thickness meter.

## Result and discussion

Fig. 1 shows Ir loading and cell voltage as a function of time. The vertical arrows on the cell voltages show determination of electrochemical properties with 3-electrode electrochemical cell. After the determination, electrolysis continued. The change of cell voltages between before and after the determination might be affected by the change of behavior of the toluene adsorbed on the electrode. The Ir loading decreased with time, and the consumption rate of electrode for 700°C of the thermal decomposition temperature was lower than that for 500°C. The lifetimes, which were the time at 4 V of the cell voltage, tested electrode for 500°C and 700°C of thermal decomposition temperature were 250 h and 350 h, respectively. Therefore, high temperature thermal decomposition would decrease Ir consumption rate and extended lifetime of electrode.

Fig. 2 shows polarization curves of electrode for 700°C of thermal decomposition temperature before and after electrolysis in 1 M H<sub>2</sub>SO<sub>4</sub> with and without saturated TL. Before electrolysis, the decrease of current density by TL contamination was hardly observed. However, the current density decreased by TL contamination after electrolysis. Therefore, affinity of TL on the electrocatalyst might increase with consumption of the electrocatalyst during electrolysis and the difference of the current density with and without TL increased during electrolysis.

As one type efficient and clean energy converters, fuel cell has attracted much attention in recent years [1]. However at the current stage of technology, the cost is one of the big obstacles hindering the commercialization of fuel cells. Especially, the high noble metal loading required for the oxygen reduction reaction (ORR) occurred at the cathode region (0.4 mg cm<sup>-2</sup> Pt for ORR, 0.05 mg cm<sup>-2</sup> Pt for the anode reaction [2]). In order for the fuel cell to replace the internal combustion engines currently used, significant decrease in the cost is urgently required. Very recently, H<sub>2</sub>O<sub>2</sub> replaced O<sub>2</sub> as oxidant has been investigated in several low-temperature fuel cells, particularly in air-free environments (space or underwater) [3, 4]. That is due to its easy handling, storage, faster reduction kinetics than oxygen and higher standard reduction potential than oxygen [5, 6]. Recent study has also shown that H<sub>2</sub>O<sub>2</sub> as a powerful oxidant could significantly increase the power density of a fuel cell. Among several types of electrocatalysts for H<sub>2</sub>O<sub>2</sub> reduction, Co<sub>3</sub>O<sub>4</sub> have been conceived as a promising cost-effective and scalable alternative, in place of precious metals, for H<sub>2</sub>O<sub>2</sub> electroreduction.

A facile synthesis of morphology-controlled Co<sub>3</sub>O<sub>4</sub> nanostructures through the solvothermal synthesis was successfully demonstrated (Figure 1). With the control of the solvent composition, we have obtained five different nanostructures (nanosheet, nanowire, ultrafine nanowire net, nanobelts, and nano-honeycombs). The ethanol introduced in the synthesis processes plays an important role on the crystal size, morphology, as well as their catalytic performance for H<sub>2</sub>O<sub>2</sub> electroreduction. The sample prepared in the 2:1 C<sub>2</sub>H<sub>5</sub>OH/H<sub>2</sub>O solvent displays an ultra-fine nanowire net morphology, which possesses an open, porous nanostructure with a large surface area. These characteristics of Co<sub>3</sub>O<sub>4</sub> nanostructures make it facilitate electrons/ions transferring and enhance the catalytic efficiency when used as an electrode. The resulting electrode shows better performance for H<sub>2</sub>O<sub>2</sub> electroreduction in an alkaline medium in terms of the catalytic activity than Co<sub>3</sub>O<sub>4</sub> nanowire array electrode prepared in the pure water solvent. In the solution of 3.0 mol L<sup>-1</sup> KOH+0.5 mol L<sup>-1</sup> H<sub>2</sub>O<sub>2</sub>, the current density at -0.4 V could maintained at 0.214 A cm<sup>-2</sup> during the test period. This simple solvothermal method has a great potential for the preparation of morphology-controlled Co<sub>3</sub>O<sub>4</sub> nanostructures due to its facile synthesis, low cost, especially high performance for H<sub>2</sub>O<sub>2</sub> reduction.

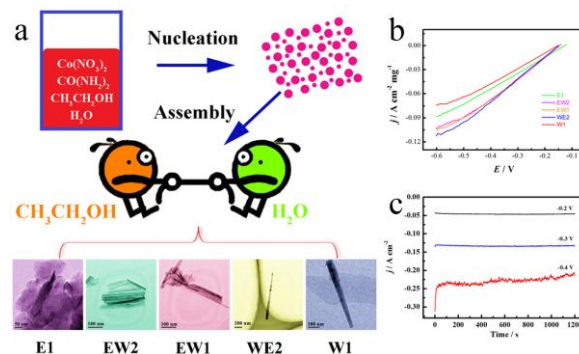

Figure 1 (a) Schematic diagram showing the mechanism for the formation of different nanostructures Co<sub>3</sub>O<sub>4</sub>. (b) The comparison of the as-prepared Co<sub>3</sub>O<sub>4</sub> nanostructures in the growth solution with different C<sub>2</sub>H<sub>5</sub>OH/H<sub>2</sub>O volume ratios. Chronoamperometric curves for H<sub>2</sub>O<sub>2</sub> reduction on the as-prepared Co<sub>3</sub>O<sub>4</sub> using C<sub>2</sub>H<sub>5</sub>OH/H<sub>2</sub>O volume ratio 1:2 (WE2) at different potentials.

maruyama@omtri.or.jp

Vanadium redox flow batteries (VRFBs) have attracted much interest as a promising electrical energy storage system due to their suitability for large-scale energy storage and capability to withstand fluctuating power supplies. The slow reaction rate of the electrode reactions is a serious problem in VRFB technology, which has to be overcome to improve the efficiency of the VRFB. Recently, the high catalytic activity was found at a carbonaceous thin film with Fe and four nitrogens (Fe–N<sub>4</sub> site) combined in a carbon matrix in the square-planar configuration and exposed to the surface [1]. The carbonaceous thin film was supported on cup-stack carbon nanotube (CSCNT). In this study, we investigated the influence of the amount of loading on the enhancement of the VRFB positive electrode reactions.

The *m*:1 (*m* = 0.1, 0.2, 0.5, 1) weight ratio mixture of iron phthalocyanine (FePc) powder and CSCNT was put in a crucible with a cap and heat-treated at 800 °C after raising the temperature at 1 °C min<sup>−1</sup> in an argon atmosphere. A treatment with an acid solution was carried out to remove any soluble metallic species from the surface. The obtained sample was then labeled CFePc*m*-800. The sample was characterized by a transmission electron microscope (TEM), X-ray photoelectron spectroscopy (XPS). The pore structure was examined by the nitrogen adsorption isotherm and the X-ray absorption fine structure (XAFS) at the Fe-*K* edge was measured to investigate the local structure around Fe.

Figure 1 shows the TEM images of CSCNT and CFePc1-800. The carbonaceous thin film derived from FePc was observed as well as aggregates of Fe. Figure 2 shows the relationships between the electrode potential and the current for the VO<sub>2</sub><sup>+</sup> reduction and VO<sub>2</sub><sup>2+</sup> oxidation. The VO<sub>2</sub><sup>2+</sup> oxidation current was increased by the coating between 0.8 and 1.0 V, but decreased above 1.0 V to be nearly half with an increase in *m* up to 1. In contrast, the VO<sub>2</sub><sup>+</sup> reduction current was significantly increased and reached the maximum at *m* = 0.2. The dependency on the amount of loading will be discussed based on the results on the specific surface area, the electrochemically active area measured by the cyclic voltammogram, the surface Fe concentration measured by XPS, the local structure around Fe.

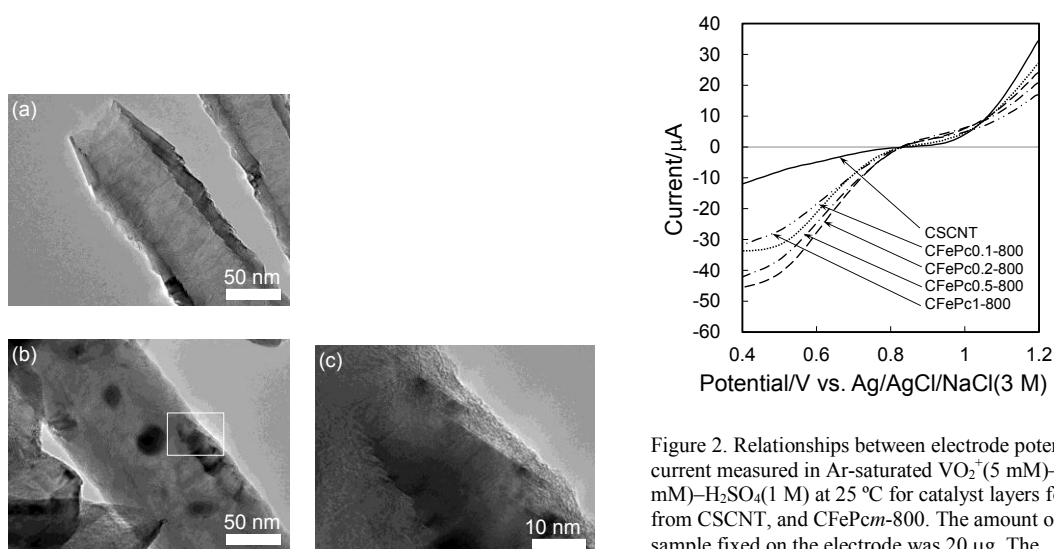

Figure 1. TEM images of (a) CSCNT and (b) CFePc1-800. Figure 1(c) shows an expanded image of the enclosed area in Figure 1(b).

Figure 2. Relationships between electrode potential and current measured in Ar-saturated VO<sub>2</sub><sup>+</sup> (5 mM)–VO<sub>2</sub><sup>2+</sup> (5 mM)–H<sub>2</sub>SO<sub>4</sub> (1 M) at 25 °C for catalyst layers formed from CSCNT, and CFePc*m*-800. The amount of the sample fixed on the electrode was 20 μg. The geometric electrode surface area was 0.071 cm<sup>2</sup>. The potential scan rate was 10 mV s<sup>−1</sup>. The rotation rate of the electrode was 2000 rpm.

# Preparing electrocatalysts for energy conversion by inkjet printing and photonic curing in one fabrication process

Andreas Lesch, Victor Costa Bassetto, Hubert H. Girault  
École Polytechnique Fédérale de Lausanne, Switzerland  
andreas.lesch@epfl.ch

Searching for new electrocatalysts gains in importance due to upcoming changes in the power grid, in particular with the integration of several electrochemical energy conversion and storage systems including fuel cells, electrolyzers and redox flow batteries. The underlying electrochemical reactions, for instance the oxygen reduction reaction (ORR) or the oxygen evolution reaction (OER), take place in catalyst layers in which electrocatalysts represent the active sites. Currently, precious metals (e.g. Pt) and precious metal oxides (e.g. IrO<sub>2</sub> and RuO<sub>2</sub>) supported on carbon black are the most commonly used electrocatalysts for the ORR and OER, respectively.

However, the use of such compounds is usually connected with high material cost, partially limited reserves and in case of ORR catalysts even low catalytic activity. Therefore, many efforts are made to either reduce the amount of required precious metals and to increase at the same time the catalyst utilization or to modify or replace the noble catalysts by alternative non-precious, low cost materials. Binary or ternary systems have found much attraction, but catalytic activity of such complex systems is difficult to predict. One approach is to prepare combinatorial catalyst libraries that can be screened for instance by optical methods or scanning electrochemical microscopy to identify the most active compositions.

One approach to prepare such libraries is made by dispensing metallic nanoparticle solutions or inks containing metal precursors by using inkjet printing.<sup>[1-3]</sup> Inkjet printing is a digital, mask-less material deposition technique where picoliter droplets decorate with micrometer resolution those substrate areas where a specific functionality is targeted. After the printing process, the ink is converted into a solid composition by thermal and/or chemical means to evaporate ink additives and to cure nanoparticles but also to favor the chemical reduction of metal cations. The applied temperatures for the latter can easily reach several hundred degrees Celsius requiring specific substrates and the temporary placement of the printed patterns inside a furnace. Recently, photonic curing has been introduced as a powerful non-equilibrium thermal post-processing tool for printing applications.<sup>[4]</sup> Thanks to light pulses in the millisecond range, generated from a Xenon flash lamp, the heat transferred during catalyst formation is mainly located in the ink and just on the substrate surface allowing the utilization of even low temperature substrate materials.

In this contribution, new approaches for employing an inkjet printer with three printheads and integrated photonic curing station for the inkjet printing and in-line photonic curing of various nanoparticulate and metal precursor inks (e.g. Pt, IrO<sub>2</sub>, Co<sub>3</sub>O<sub>4</sub> and Cu) will be introduced to obtain electrocatalysts, combinatorial libraries and catalyst layers.

# Pd-based bimetallic nanocatalysts for alkaline glucose electrooxidation and fuel cells application

Cheng-Chuan Chen, and Lin-Chi Chen\*

Department of Bio-Industrial Mechatronics Engineering, National Taiwan University

No. 1, Sec. 4, Roosevelt Road, Taipei 10617, Taiwan

[chenlinchi@ntu.edu.tw](mailto:chenlinchi@ntu.edu.tw)

Direct glucose fuel cell (DGFC) is one of the potential green energy sources in the future because glucose, a six carbon sugar, is renewable, abundant and non-toxic in nature. One molecule of glucose can theoretically release 24 electrons and provide  $2870 \text{ kJ mol}^{-1}$  through a complete glucose oxidation reaction. Recently, several noble metal catalysts have been developed to improve the catalytic activity of DGFC [1,2]. However, only partial oxidation of glucose occurs practically and two electrons are released per molecule. This indicates that there is still plenty of room to improve the glucose catalytic performance. For this reason, the extensive investigation of electrocatalysts catalyze GOR has been made to generate a higher electricity. Very recently, there are many studies focus on finding an idea catalyst to improve the GOR efficiency. In this respect, the approach to find out a new electrocatalyst with the high catalytic activity and stability is a potential research direction in DGFC. Catalyst material often plays a determining role in fuel cell performance, and platinum (Pt) has long been a main and indispensable component for most anode catalysts, including the ones used for DGFC study. However, Pt is a costly noble metal and is easy to be self-poisoned by adsorbed intermediates. By this reason, palladium (Pd) based catalysts have been studied for electrocatalytic GOR in DGFC. It also has been known that the catalytic activity of Pd monometallic catalyst is still not sufficient to reach the notably higher GOR current density. Hence Pd-based bimetallic catalysts are used in alkaline glucose electrooxidation to reach a higher GOR current density through a synergistic effect [2]. This presentation focuses on studying the effects of carbon supported bimetallic Pd-based catalysts (Pd-Bi/C and Pd-Ni/C) prepared by an alkaline polyol synthesis and their application in DGFC. Physicochemical properties (e.g., XRD, XPS, and HR-TEM) and electrochemical behaviors (e.g., CV and CA) are studied to understand how catalysts affect the GOR performance. We also discuss the influence of surfaces properties of carbon supports on Pd catalyzed glucose in this work [3]. Compared to the Pd/C, the prepared catalysts provide the higher electrochemical surface area, improved catalytic activities, and better stability.

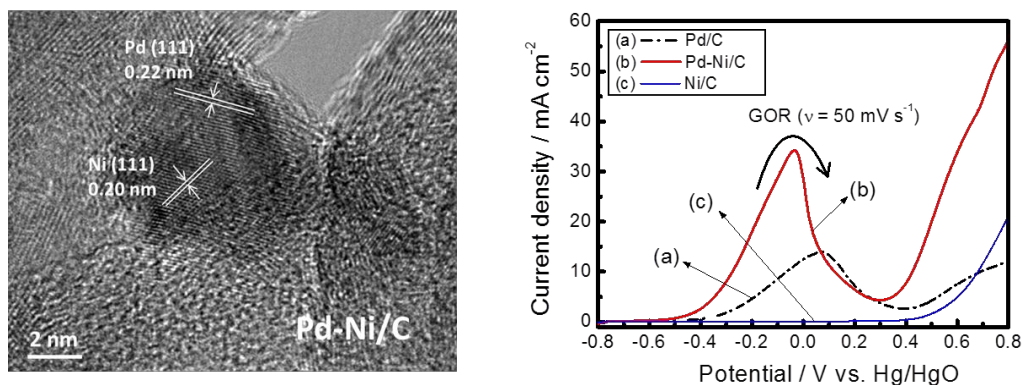

Fig. 1 Alkaline GOR performance of carbon supported Pd<sub>shell</sub>-Ni<sub>core</sub> electrocatalysts (Pd-Ni/C).

Martensstrasse 7, D-91058 Erlangen, Germany  
schmuki@ww.uni-erlangen.de

As a supercapacitor material, the gold standard is RuO<sub>2</sub> as it provides intrinsically fast, high and reversible intercalation properties and a comparatively high electron conductivity. For example, hydrous ruthenium oxide (HRO) has been reported to show a high mass specific capacitance of 600 to 750 F g<sup>-1</sup>. Nevertheless, the theoretical specific capacitance of 1400 to 2200 F g<sup>-1</sup>, is even higher. In order to more efficiently exploit the expensive HRO it should be ideally dispersed as a nanoparticle of only a few nm diameters on a suitable electron-conductive scaffold. In order to provide an ideal scaffold electrode geometries that provide an optimized ion diffusion path into the solid and through the electrolyte are desired. To address these requirements recently self-ordered TiO<sub>2</sub> nanotubular arrays have been explored directly for their super capacitive performance. Previous findings however show a limited success which is due to the comparably small and sluggish red-ox switching properties of TiO<sub>2</sub> (in all crystal polymorphs) and even more problematic is the limited electrical conductivity of the TiO<sub>2</sub> nanotubes

In this work we demonstrate a procedure that allows a highly conformal coating of self-organized TiO<sub>2</sub> nanotubes with a graphite-like thin carbon layer. This well conducting coating then can be further modified using established carbon chemistry to anchor an active RuO<sub>2</sub> nanoparticle layer on the tube walls. Used as 3D pseudocapacitor electrodes capacitance value of up to 87 times higher than plain TiO<sub>2</sub> nanotube arrays and a very high yield of utilization of RuO<sub>2</sub> can be reached. Additionally this configuration shows an excellent long-term cycling stability with only 4.4% decrease of initial capacitance after 1000 cycles. A key to this improvement is that here introduced treatment reduces the electrical conductivity of an anatase tube drastically. This opens up a platform to novel applications and enhanced functionality of TiO<sub>2</sub> nanotubes.

# One-step hydrothermal route to fabricate novel $\text{ZnIn}_2\text{S}_4/\text{g-C}_3\text{N}_4$ heterojunction photocatalysts with highly-efficient visible light response

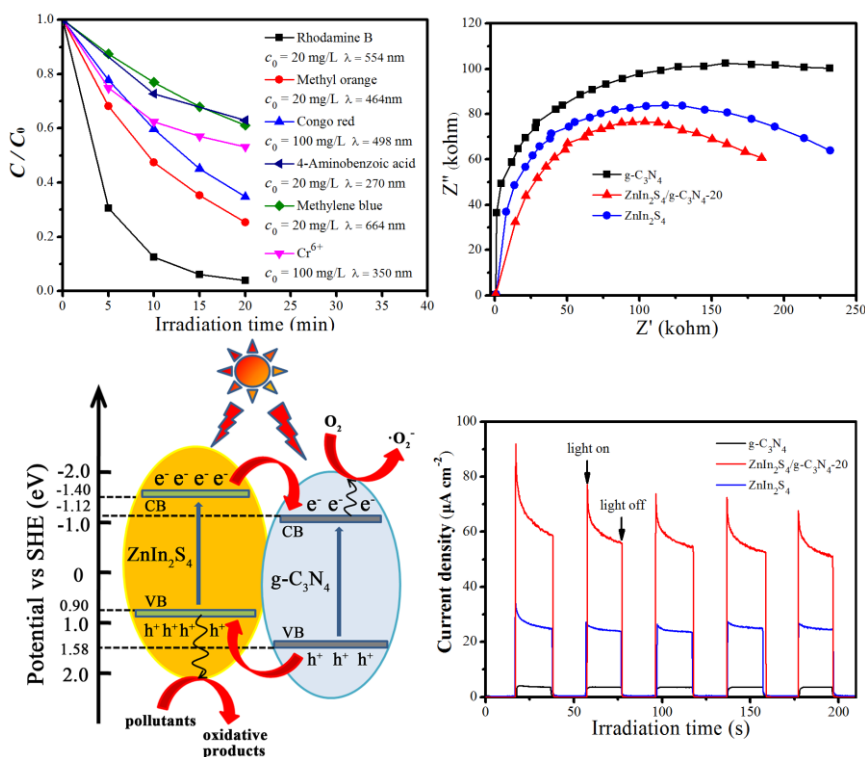

Xiaoheng Liu\*, Wei Chen

Key Laboratory of Education Ministry for Soft Chemistry and Functional Materials, Nanjing University of Science and Technology, Nanjing 210094, China

No. 200 Xiaolingwei street, Nanjing, Jiangsu province, China

xhliu@mail.njust.edu.cn

Heterogeneous  $\text{ZnIn}_2\text{S}_4/\text{g-C}_3\text{N}_4$  hybrid composites, as highly-efficient visible-light-driven photocatalysts, were firstly fabricated by a simple one-step hydrothermal route; wherein the porous  $\text{g-C}_3\text{N}_4$  ultrathin nanosheets (NSs) serve as platform supporting to in-situ immobilize the cubic  $\text{ZnIn}_2\text{S}_4$  nanoparticles (NPs). The resultant  $\text{ZnIn}_2\text{S}_4/\text{g-C}_3\text{N}_4$ -20 composite with 20 mg  $\text{g-C}_3\text{N}_4$  exhibits efficient photocatalytic activities, excellent photo-stability and versatile photocatalytic abilities towards organic dye degradation and Cr (VI) reduction. The significant enhancement of photocatalytic activity is attributed to the effective separation of photo-generated charge carrier pairs based on the construction of close heterogeneous interface, which can obviously lengthen the life span of holes and electrons pairs. The effective charge transfer from cubic  $\text{ZnIn}_2\text{S}_4$  to porous  $\text{g-C}_3\text{N}_4$  ultrathin NSs was confirmed by photoluminescence quenching, transient photocurrent-time (I-t) curves and electrochemical impedance spectroscopy (EIS) Nyquist plots.

# A method for the simultaneous cleansing of H<sub>2</sub>S and SO<sub>2</sub>

K. Petrov<sup>a</sup>, D. Uzun<sup>a</sup>, E. Razkazova-Velkova<sup>b</sup>, V. Beschkov<sup>b</sup>,

<sup>a</sup>*Institute of Electrochemistry and Energy Systems „Acad. Evgeni Budevski”, Bulgarian Academy of Sciences, Acad. G. Bonchev Str., Bl.10, 1113 Sofia, Bulgaria*

<sup>b</sup>*Institute of Chemical Engineering, Bulgarian Academy of Sciences, Acad. G. Bonchev Str., Bl. 103, 1113 Sofia, Bulgaria*

A method for the simultaneous electrochemical purification of hydrogen sulfide and sulfur dioxide from Black Sea waters or industrial wastes is proposed. Fundamentally the method is based on the electrochemical affinity of the pair H<sub>2</sub>S and SO<sub>2</sub>. The reactions (oxidation of H<sub>2</sub>S and reduction of SO<sub>2</sub>) proceed on proper catalyst in a flow reactor, without an external power by electrochemical means. The partial curves of oxidation of H<sub>2</sub>S and reduction of SO<sub>2</sub> have been studied electrochemically on different catalysts (CoPc/C; La<sub>1.3</sub>Sr<sub>0.7</sub>NiO<sub>4</sub>; Bulk Graphite; and 6% Pt/C). Following the additive principle the rate of the process has been found by intersection of the curves, shown in Fig.1.

Fig. 1. Polarization curves for the oxidation of H<sub>2</sub>S (1) and the reduction of SO<sub>2</sub> (2).

The overall process rate has been studied in a flow type reactor. Similar values of the process rate have been found. This is a proof of the electrochemical mechanism of the reactions. As a result the electrochemical method at adequate conditions is developed. The process is able to completely convert the initial reagents (concentrations C<sub>H<sub>2</sub>S</sub>, C<sub>SO<sub>2</sub></sub> = 0), which is difficult given the chemical kinetics. Finally we should state, that the best application in our view, is the cleansing of H<sub>2</sub>S in Black Sea waters together with SO<sub>2</sub> containing gases from coal power plants located on the shore. The preliminary calculations show that 1 m<sup>3</sup> Black Sea water (C<sub>H<sub>2</sub>S</sub>=8 mg.l<sup>-1</sup>) converts SO<sub>2</sub> from 3 m<sup>3</sup> waste gas C<sub>SO<sub>2</sub></sub>=1000ppm).

\*Email: [i.pikaar@uq.edu.au](mailto:i.pikaar@uq.edu.au)

Hydrogen sulfide induced sewer corrosion is a notorious problem that costs wastewater utilities billions of dollars each year globally [1]. Two of the most commonly used chemical abatement strategies by the water industry are oxygen injection and periodic caustic shock-loading for killing/removal of the sewer biofilm responsible for hydrogen sulfide generation [2]. Although these two strategies are implemented successfully at full-scale, the frequent transport, handling, and storage of pure oxygen and caustic soda often come with serious safety concerns as well as with negative public image. Hence, on-site production approaches can alleviate many of these concerns.

Here we present a novel three-compartment electrochemical cell which simultaneously produces caustic and oxygen from sewage (Figure 1). The middle compartment is fed with a concentrated NaCl solution and is separated from the anode by an anion exchange membrane and from the cathode by a cation exchange membrane, creating a chloride flux from middle compartment to anode, and a sodium flux from middle compartment to cathode. Sewage was continuously fed to the anode and oxygen was continuously generated in the anode compartment. Cathode was operated in a batch mode where water was reduced to H<sub>2</sub> and OH<sup>-</sup> which recombines with the Na<sup>+</sup> to form NaOH.

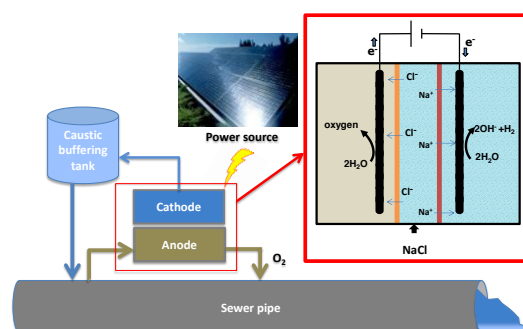

Fig. 1. Simplified schematic overview of the concept

Caustic was efficiently produced from sewage over a period of 12 weeks with an average Coulombic efficiency (CE) of 84.1±1.1% at practically relevant caustic strengths. Equally important, dissolved oxygen (DO), was continuously produced in the sewage at a CE of ~50%, a significantly higher efficiency than conventional oxygen injection (i.e. <30%) [3]. This continuous aeration of the sewage benefits sewer pipes downstream by maintaining aerobic conditions and oxidizing residual sulfide. The obtained DO levels in sewage ranged between 3.8-12.6 mg/L O<sub>2</sub>, depending on the current-to-flow ratio. The two produced chemicals can be applied to sewer pipes alternatively with caustic shock-loading to remove sewer biofilms and oxygen suppressing biofilm development between caustic shocks leading to prolonged biofilm recovery and thus reducing the required frequency for caustic addition. The only inputs to this system are electricity and sodium chloride. In a practical situation, the process can be driven by a solar panel, making it a very sustainable solution. It also eliminates the safety issues related to the transport and storage of concentrated chemicals. To the author's best knowledge, this is the first time that a sustainable solution is proposed to alleviate the notorious and costly problem for water utilities globally.

## Abstract:

Looking for engineers, physicists and robot applications use to consider polymeric bilayer actuators (or artificial muscles) as low reliable devices for soft tools or soft robotic developments. Here we present the electronic-mechanical (movement rate and position) characterization of a polypyrrole/tape bilayer bending actuator and how it was validated with a electronic proportional-integral (PI) control system. The angular rate of the movement results a linear function of the applied current and the described angle is a linear function of the consumed charge. The polypyrrole film was synthesized in presence of dodecylbenzene-sulphonate (DBS<sup>-</sup>) and ClO<sub>4</sub><sup>-</sup> anions: it exchanges cations during subsequent oxidation/reduction reactions. The correlation coefficients overcame 0.99: electro-chemo-mechanical polymeric motors are full reliable for technological applications. The electrochemical model explaining the relationships between charge, film volume variation, mechanical work, force and displacement. The applied engineering design requires new materials giving multifunctional devices: the best design is the one involving the lower number of components.

In recent years there has been a growing search for clean, catalytic and environmentally friendly methodologies in organic synthesis. To tackle these issues, an electrosynthetic methodology can be applied. Electrochemical syntheses mostly need fewer steps, produce less waste, provide a cheaper reagent and require less auxiliaries [1]. However, a major drawback is that those electrosynthetic processes require very negative electrode potentials that are inadequate for use in industrial production processes due to exuberant energy costs. Attempts to reduce the large overpotentials are directed towards improving catalytic activity of the electrode materials.

In this work, the link between the morphology of the catalyst material and the electrosynthetic pathway was investigated. In a first step, nanoparticles of transition metals (Ag, Cu, Pd, Ni, Pt and Au) were electrochemically deposited and the effect of their morphological properties (particle size, porosity, ...) on the electrochemical syntheses were studied. The nature of the nanoclusters were tuned by changing the electrolyte composition and the deposition parameters. In a second step, core-shell electrocatalysts were constructed with Ag (the most active electrode material) as a shell metal and Cu as a core metal. We have previously shown the potential catalytic enhancement of comparable core-shell NP's prepared by galvanic displacement towards ORR [2].

The described strategy was evaluated for the intermolecular cyclisation of allyl 2-bromobenzyl ether until benzopyran, an important building block in pharmaceutical industry. The classical organic approach currently used in industry is characterized by a low conversion and poor environmental conditions due to the use of harmful solvents such as tributyltin hydride [3].

Self-powered systems have been developed to integrate variable devices into a standalone system with multiple functions, including sensing, communication, computation, *etc.* The wireless, miniaturized and the large number of components in the system require a renewable, sustainable and clean power supply, and energy harvesting from the ambient environment will be a perfect solution for this problem. In this regard, the triboelectric nanogenerator (TENG) was recently invented to convert the mechanical energy into electricity, based on the coupling effect of contact electrification and electrostatic induction. Here in this work, we established a fully-integrated self-powered smart window composed of a dual-mode TENG and an ECD. The entire device was a transparent, multi-layered structure, which was compatible with the smart window structure. The ECD was composed of Prussian blue (PB) nanoparticles and zinc hexacyanoferrate (ZnHCF) nanocubes as the electrochromic material and the ion storage layer, respectively. By operating with conventional electrochemical workstation, the maximum reversible change in transmittance ( $\Delta T$ ) of 32.6% could be achieved with respect to an external DC voltage. The TENG consisted of a multi-layered structure with micro-patterned polydimethylsiloxane (PDMS) thin films and transparent electrodes, which could be employed for harvesting the kinetic energy from wind impact and water droplet, with an optimized output power of 130 mW/m<sup>2</sup>. By assembling the two devices on the same substrate, the self-powered smart window system was successfully realized with a transmittance change of up to 32.4% with visualized color variations as well, which could compete with the results demonstrated by the electrochemical workstation. This work sheds light on motion-driven electrochemical reactions and paves the way for a promising applications of the TENGs, which will push forward the development of self-powered systems. This research is a substantial advancement towards the practical application of nanogenerators and self-powered systems, and it paves the way for the development of fully independent smart windows or high-performance displays.

## Symposium 10

The textile industry produces large amounts of waste water during washing and dyeing containing large amounts of dyes which are not fixed on the surface of fibers, and as a result are eliminated along with the coloration of textile effluents (water courses, affecting its transparency, gas solubility and may have carcinogenic and mutagenic properties) [1]. As an innovative alternative, the electrochemical processes for treating wastewater containing organic matter have been proposed. The application of electrochemical technologies for wastewater treatment is benefiting from advantages such as versatility, environmental compatibility and potential cost effectiveness [2,3]. This technique has been recently used for decolorizing and degrading dyes from aqueous solutions by several scientific groups [1,3]. A large variety of electrochemical systems have been tested for the treatment of dyeing wastewaters by EO: conventional three-electrode cells with two-compartment or one-compartment and divided or undivided two electrode cells or tank reactors have been widely utilized. Other authors have employed flow cells with parallel electrodes and flow plants with a three-phase three-dimensional electrode reactor or a bipolar trickle tower reactor Fig. 10 in Ref. [1] illustrates some electrochemical plants and cells designed for this technique operating in batch mode to attain the maximum solution decontamination. The cells are divided or undivided and contain monopolar and sometimes bipolar electrodes.

The hydrodynamics of the cell plays a fundamental role in the mass transport towards the electrodes to efficiently oxidize organics pollutants. However, few attempts have been published until now [4], using flow cells with planar electrodes in a serial configuration increasing oxidation rate of pollutants. In this frame, we propose the use of electrochemical technology as an alternative for removing synthetic dyes (Remazol Red RB (RRB), Novacron Yellow (NY) from aqueous solutions by employing two kinds of flow cell systems (single flow cell (SFC) and dual flow cell (DFC) investigating the influence of operating parameters using as electrocatalytic materials: Ti/Pt, Ti/Pt-SbSn, Ti/IrO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> and boron doped diamond (BDD) electrodes. The results obtained in SFC system allow to identify the best experimental conditions for applying in DFC, that result in high current efficiency and low energy-cost, demonstrating that the use of plants with different stacks favors the complete elimination of organic pollutants in the effluents when electrochemical reactors with non-active and active electrodes are combined.

t.homma@waseda.jp

Electrochemical processes play a key role for fabricating various micro and nano devices and systems. While they have been widely used featuring their controllability and capability to form uniform deposits onto wide, non-flat surfaces, further precise control is required for achieving higher performances as well as improving the fabrication processes. These processes are quite complicated since numbers of factors simultaneously affect the deposition reactions taking place at solid-liquid interface where analytical tools are limited. For this, we focused on surface enhanced Raman spectroscopy (SERS) and proposed “plasmonic sensors” which have designed nanostructures at surface to achieve very high enhancement effect, and applied them to analyze various processes [1,2]. In addition, we also applied theoretical approaches such as density functional theory (DFT) calculations to investigate the processes in combination with the Raman spectroscopy [3]. In this paper, results of these approaches to analyze electrochemical fabrication processes will be introduced.

We have developed two types of the plasmonic sensors as shown in Fig. 1. The “reflection” type sensor consists of metal which is active for plasmonic enhancement, such as Ag, Au, and Cu, with centrifuge-grooved nanostructure. The pitch of the grooves was designed according to the wave length of the incident laser to maximize the enhancement, and the sensors can be directly used as substrates (working electrode) for the electrochemical processes (Fig.1(a)). On the other hand, “transmission” type sensor (Fig. 1(b)) can be applied to various processes and materials regardless of the variation in substrates. By using these sensors, we analyzed electrodeposition and electroless deposition processes to form various nanostructures, focusing upon the behaviors of the species, such as additives and reductants, at the deposition sites. In addition, we have also developed a system to analyze the behavior of additives in the pores of through silicon via (TSV). A model-pore was fabricated using a Si substrate modified with metal nanoparticles, which was covered with a trench-shaped structure consisting of poly(dimethylsiloxane) (PDMS). The incident laser for the SERS measurement was focused at the substrate surface through the PDMS structure, and it was confirmed that the signal of additives could be detected in situ in high sensitivity, without interference of the signals originated from PDMS, and their behavior was investigated in detail.

This work was financially supported in part by "Development of Systems and Technology for Advanced Measurement and Analysis," Japan Science and Technology Agency, and Grant-in-Aid for Scientific Research (A), MEXT, Japan.

Microbial fuel cell (MFC) is an emerging technology that has gained researchers' attention because they can simultaneously treat wastewater and recover energy. The MFC converts the chemical energy contained in organic matter into electricity using microorganisms that oxidize the soluble organics, transferring electrons to the anode. Several factors influence on the performance and the application of MFC technology, such as operating conditions, reactor configuration, membrane type and external resistance. However, the performance and the costs of electrodes are one of the key points for the application of MFC technology and information is needed on their long-term stability. Therefore, in this work the aim is to determine the performance of different types of carbon electrodes using a synthetic and winery wastewater as substrates in a dual chamber MFC. Carbon felt, carbon cloth, carbon foam and carbon paper were used as electrodes in anode and cathodes.

Results demonstrate that electricity can be efficiently produced with both types of wastewater producing 100 mV of average voltage with the best electrode. Biological treatment was efficient in terms of COD removal with daily removals around 2220 mg L<sup>-1</sup> d<sup>-1</sup> (55%) for the synthetic wastewater and around 700 mg L<sup>-1</sup> d<sup>-1</sup> (10%) for the winery waste. The lower efficiency observed in MFC fed with winery wastewater can be explained taking into account that the winery wastewater contains important concentrations of recalcitrant species which are difficult to be biodegraded.

In this study, the MFC operated with carbon felt produced significantly more power than other carbon electrodes. The morphology, surface area of electrodes influenced in microbial adhesion consequently in biological treatment and power generation. Therefore, the choice of electrode material may have significant consequences for biofilm-electrode formation and current production in MFC technology pure cultures.

In this work we studied the remediation of wastewater containing bovine slurry from a Chilean meat producer company, using electrochemical advances oxidation process (EAOPs).

On the one hand, we studied the degradation of organics from wastewater with a BDD/stainless steel system by electrochemical-oxidation. A rapid decolorization and mineralization was reached at short time of electrolysis without adding supporting electrolyte and in the presence of sodium chloride or sodium sulphate.

On the other hand a combination of anaerobic biological treatment followed by solar photoelectro-Fenton (SPEF) treatment was performed. Bio Assays were performed in an anaerobic bioreactor for 30 days, thermostated at 35 °C. On the other hand, the electrolysis was performed in an open electrochemical cell of 400 mL, with temperature control of the solution at 35 °C using a current density of 50 mA cm<sup>-2</sup>, initial pH of 3.0, with a concentration of catalyst Fe<sup>2+</sup> 1.0 mM and 0.05 M Na<sub>2</sub>SO<sub>4</sub> as supporting electrolyte, exposed to direct sunlight. An air diffusion cathode of carbon-PTFE and an anode of boron doped diamond (BDD) were used, both electrodes with an area of 2.5 cm<sup>2</sup> and gap 1 cm. The slurry samples were treated separately, by anaerobic digestion and SPEF. By anaerobic digestion, a 90% of COD removal was reached, after 30 incubation days with a production of methane gas of >100 mL. By SPEF, almost a complete mineralization was achieved after 4 hours of electrolysis. Considering the good results obtained by each treatment separately, wastewaters were treated by combining both methods. First, 83% COD decay was reached by anaerobic treatment producing >100 mL de methane. Then, by SPEF, a complete remotion of organic compounds was obtained.

By the use of EAOPs, water without color and organic compounds was produced by electrochemical processes or the combination with biological process.

# Flow-through Electrochemical Cells for Efficient Dye Removal

Minghua Zhou\*, Liang Ma, Weilu Yang, Gengbo Ren, Fangke Yu

Key Laboratory of Pollution Processes and Environmental Criteria of Ministry of Education,  
College of Environmental Science and Engineering, Nankai University,  
94 Weijin Road, Tianjin 300071, P. R. China  
E-mail: zhousmh@nankai.edu.cn

Many environmental electrochemical methods have showed promising applications in the area of biorefractory and toxic pollutants abatement due to their high efficiency and environmental viability, especially electrochemical advanced oxidation processes (EAOPs) that generate powerful hydroxyl radicals [1, 2]. Among which, electro-Fenton process is a promising alternative, which is based on the in-situ electrogeneration of  $\text{H}_2\text{O}_2$  by the oxygen reduction reaction, and has been reported to be effective for the degradation of phenols, dyes, pesticides, pharmaceuticals, and personal care products (PPCPs).

In most of the EAOPs studies, flat plate electrodes are used in flow-by mode. However, this flow cells would prevent rapid reaction rates of contaminants due to diffusional limitations, and would require numerous flat plate electrodes configured in parallel to obtain an adequate specific surface area for contaminant removal. Besides the reactors explorations using three-dimensional electrodes [3], the research on the development of novel electrochemical cells operated in a flow-through mode has being attracted considerable interests due to the significant enhancement in mass-transport rates of contaminants.

In this work, some novel flow-through electrochemical cells were developed for efficient dye removal. A simple modification method was used to modify graphite felts cathode to improve degradation performance. The cathode was characterized by various tests including scanning electron microscope and linear sweep voltammetry, and the electro-generation of hydrogen peroxide on this electrode was optimized as a function of pH, current density and oxygen sparge rate. Afterwards, the generation characteristics of hydrogen peroxide in the flow-through electrochemical cells were evaluated and compared. The degradation of organic pollutants in these reactors was studied, using methylene blue and methyl orange as model pollutants. The effects of some key parameters for the treatment performance were investigated, such as  $\text{Fe}^{2+}$  concentration, pH, flow rate and initial dye concentration. And the possible mechanisms for cathode adsorption, oxidation, regeneration, as well as cathode lifetime were studied. Compared with the treatment in conventional electrochemical cells, this reactor demonstrated much lower energy consumption and instant clean effect, providing a new approach to enhance the decontamination efficiency.

# Electrochemical activation of environmental catalysis

Philippe Vernoux<sup>\*a</sup>

<sup>a</sup>Institut de Recherches sur la Catalyse et l'Environnement de Lyon, UMR 5256, CNRS,  
Université Claude Bernard Lyon 1, 69626 Villeurbanne, France

\*philippe.vernoux@ircelyon.univ-lyon1.fr

Electrochemical Promotion of Catalysis (EPOC), also called Non-Faradaic Electrochemical Modification of Catalytic Activity (NEMCA), is a promising concept for boosting catalytic processes and advancing the frontiers of catalysis [1]. This innovative field aims to modify *in-operando* both the activity and the selectivity of catalysts, in a reversible and controlled manner. EPOC utilizes solid electrolyte materials (ionically conducting ceramics) as catalytic carriers. Ions contained in these electrolytes are electrochemically supplied to the catalyst surface and act as promoting agents to modify the catalyst electronic properties in order to achieve optimal catalytic performance. It thus provides a unique means of varying promoter levels at the metal surface under reaction conditions by simply changing the potential of the catalyst film. The main advantage of EPOC is that the electrochemical activation magnitude is much higher than that predicted by Faraday's law. Therefore, EPOC requires low currents or potentials. Moreover, promoting species such as  $O^{2-}$  cannot be formed via gaseous adsorption and cannot be easily dosed by chemical ways. The EPOC technology consists in the implementation of catalysis in an electrochemical cell by using electrochemical catalysts which consist of a catalytic layer interfaced on an ionically conducting ceramic support. The latter serves as an electrically controlled source or sink of ionic promoter species that activate and modulate the behavior of the catalytic surface. Figure 1a displays a typical EPOC reactor. The catalytic layer, typically 40 nm to 10  $\mu m$  thick, is deposited on a dense solid electrolyte membrane (Figure 1a). This catalytic layer must be electronic conductor to allow the polarization. Therefore, the catalyst is also an electrode and is then named catalyst-electrode. A counter-electrode and a reference electrode, both catalytically inert, are deposited on the other side of the membrane (Figure 1a). An electrical current density (1-500  $\mu A/cm^2$ ) or potential ( $\pm 2$  V) is applied between the catalyst and the counter electrode. The reactants are co-fed over the porous electrochemical catalytic layer. Figure 1b displays a typical example of an EPOC experiment for the propane deep oxidation. The electrochemical catalyst was composed of a Pt thin film deposited by Physical Vapor Deposition (PVD) on a dense membrane of Yttria-Stabilized Zirconia (YSZ), an  $O^{2-}$  ionic conductor. A positive current (from +10 up to +500  $\mu A$ ) can strongly increase the propane conversion with a non-Faradaic manner, since the activation is up to 300 times higher than that predicted by the Faraday's law through the electrochemical oxidation of propane. This lecture will give an overview of recent advances of EPOC for environmental applications, such as hydrocarbon oxidation, soot combustion and NOx abatement.

**Figure 1:** a) Schematic of an EPOC reactor and photos of an electrochemical catalyst: thin Pt catalyst-electrode / dense membrane of Yttria-Stabilized Zirconia (YSZ)/ Au counter and reference electrodes and b) Typical example of an EPOC experiment. Electrochemical catalyst: Pt (0.1  $mg/cm^2$ )/YSZ/Au,  $T=390^\circ C$ ,  $C_3H_8/O_2 = 2000$  ppm/1%.

The anodic reaction in industrial electrolysis using acidic electrolytes such as electrowinning, electroplating, and electrolytic production of thin metal film is mainly oxygen evolution, in which there are some cases where the oxygen evolution potential happens to increase with the deposition of metal oxide or oxyhydroxide when the anode is the coated titanium anode with IrO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> catalysts prepared at a high temperature more than 450 °C. This is caused by the unwanted side reaction of metal ions existing in the electrolyte; *e.g.*, Pb(II) ions are oxidized to form PbO<sub>2</sub> on the anode in electrowinning of copper, and the deposited PbO<sub>2</sub> film is partially reduced to non-conductive PbSO<sub>4</sub> during open-circuit condition.

This paper presents a novel and unique structure consisting of nano catalytic oxide particles in combination with an amorphous non-active oxide matrix, which is able to apply to an oxygen evolution anode in industrial electrolysis and suppress such unwanted side reactions. This catalyst can be prepared by a simple procedure; a precursor solution containing active and non-active metals in the form of complex ions is painted on a metal substrate followed by thermal decomposition. These metal oxides are immiscible and have a large difference in the oxide formation temperature so that the active metal oxide is formed as nano-size particles which are dispersed in the non-active metal oxide matrix.

The active metal oxide is IrO<sub>2</sub> and the non-active oxide is Ta<sub>2</sub>O<sub>5</sub> in this paper. Thermal decomposition of a precursor solution containing Ir(IV) with Ta(V) at a temperature below 650 °C results in the amorphous Ta<sub>2</sub>O<sub>5</sub> matrix, while IrO<sub>2</sub> in the matrix is generated in the crystalline or amorphous (nano-size particles) form depending on the thermal decomposition temperature. Low temperature calcination at 380 °C or less produces the hybrid structure with nano IrO<sub>2</sub> particles in the Ta<sub>2</sub>O<sub>5</sub> phase as shown in Fig. 1a, although the crystalline IrO<sub>2</sub>-contained oxide, *i.e.*, with aggregated IrO<sub>2</sub> particles, can be seen by thermal decomposition at a high temperature of 470 °C (Fig. 1b). The IrO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> nano-amorphous hybrid catalyst induces excellent catalytic activity for oxygen evolution and a high overpotential for crystallization of PbO<sub>2</sub> in acidic aqueous solutions, demonstrating that the nano-amorphous hybrid catalyst has high reaction selectivity for wanted and unwanted reactions.

*This work was financially supported by “Kyoto Area Super Cluster Program” of Japan Science and Technology Agency (JST).*

# Removal of emerging pollutants and biodegradable organic matter from wastewater by combined electrochemical -biological processes

O. Rodríguez-Nava<sup>a,b</sup>, M. A. Arellano-González<sup>c</sup>, A.-C Texier<sup>b</sup>, Ignacio González<sup>c</sup>

<sup>a</sup> *Escuela Nacional de Ciencias Biológicas, Instituto Politécnico Nacional, Departamento de Ingeniería en Sistemas Ambientales. Av. Wilfrido Massieu s/n, Unidad Profesional Adolfo López Mateos, Gustavo A. Madero, D.F. 07738, México*

*Universidad Autónoma Metropolitana-Iztapalapa, <sup>b</sup> Departamento de Biotecnología, <sup>c</sup> Departamento de Química, Av. San Rafael Atlixco 186, Col. Vicentina, Iztapalapa C. P. 09340, D. F., Mexico*

Nowadays emerging pollutants are present in natural waters, drinking water supplies and municipal wastewater, representing a serious problem in natural ecosystems due to their toxicity and causing DNA damage and oxidative stress in living organisms. Despite that, their concentrations in wastewater range from nanograms to milligrams, they are also persistent in Wastewater Treatment Plants (WWTP). The WWTP are designed for removing Biodegradable Organic Matter (BOM) through metabolic abilities of different microorganism constituting the biological consortium; these microorganisms are sensitive to the presence of these pollutants. Therefore, it is necessary to propose a pre-treatment prior to biologic reactor treatment, with the aim of eliminating selectively these pollutants and prepare an adequate feeder for the biological reactor. In this work, two kind of recalcitrant pollutants are considered: pharmaceuticals and chlorinated organic compounds and two different electrochemical pretreatment are proposed.

This work shows the feasibility of coupling an electrooxidation and biological system for removal of recalcitrant drugs (Bezafibrate, Gemfibrozil, Indomethacin and Sulfamethoxazole, BGIS) and BOM from wastewater, attaining high removal efficiencies without affecting the performance of activated sludge [1]. BGIS degradation was performed by advanced electrochemical oxidation using Boron Doped Diamond (BDD) as electrode and activated sludge process to BOM degradation in continuous reactor. The electrochemical parameters ( $1.2 \text{ L s}^{-1}$  and  $1.56 \text{ mA cm}^{-2}$ ) were chosen to operate filter press laboratory reactor, FM01-LC throughout microelectrolysis test, in order to remove drugs without decreasing BOM and chlorine concentration control to avoid bulking formation in a biological process. The wastewater previously treated by FM01-LC was fed to activated sludge to remove 100% of BGIS and 83% of BOM respectively, whereas the BGIS contained in wastewater without electrochemical pretreatment were persistent in biological process and promote bulking formation.

In the case for chlorinated organic compound degradation, the electrochemical oxidation is discarded due to the production of a polymer film at the electrode surface causes electrode deactivation. In order to avoid the problems caused by oxidation, electrochemical reductive dechlorination (electrocatalytic hydrogenolysis, ECH) has been suggested as an alternative and promising pretreatment method. The efficient dechlorination of 2-chlorophenol to phenol was achieved under electrochemical conditions where proton reduction and atomic hydrogen adsorption took place. The Pd-Ni alloy/Ti electrode (previously prepared by electrodeposition) showed the highest dechlorination efficiency (100% removal) and phenol formation (100% formation) at a potential of  $-0.40 \text{ V}$  vs  $\text{Ag/AgCl(s)/KCl(sat)}$ . The electrolysis was performed in a plate electrodes reactor (ECO-CELL). The chemical composition of the electrochemical reactor effluent was adjusted to feed a biological reactor (denitrifying process) for its complete mineralization.

# A Bifunctional Air Electrode Catalyzed by Transition Metal Ferricyanide Derivatives for an Iron-air battery

R.D., H.A. Figueredo Rodriguez, C. Ponce de León, F.C. Walsh  
*University of Southampton*  
*University Road, Southampton, SO17 1BJ*

Perovskites have been gaining importance in rechargeable metal air batteries as bifunctional air electrodes and have been gradually been considered as substitutes for noble metals such as Pt, Pd, Ir or Ru typically used as a catalyst for the air electrode [1]. The activity of the transition metal compounds found in perovskites towards the reduction and evolution of oxygen has been demonstrated at low overpotentials however, the synthesis of these materials requires elevated temperature [2].

Transition metal complexes with ferricyanide (Prussian blue derivatives) are low-cost and can be produced in the form of insoluble nanoparticles by a single room-temperature step. They are already promising bifunctional oxygen catalysts, and when combined with a very small loading of palladium ( $0.5 \text{ mg cm}^{-2}$ ), they form an air electrode with exceptional bifunctionality and durability.

The co-precipitation of  $\text{Ni}^{2+}$  with  $[\text{Fe}(\text{CN})_6]^{3-}$  was used to produce  $\text{Ni}_3[\text{Fe}(\text{CN})_6]_2$  complex as a convenient route to synthesize low cost catalyst. The resulting catalyst was mixed with Nafion® and carbon black to form a paste that was spread onto a carbon powder/paper gas diffusion layer in order to manufacture bifunctional air electrodes. The electrodes were prepared in the absence and in the presence of palladium catalyst and tested in a 3-electrode cell at 20-60 °C. The results show that  $\text{Ni}_3[\text{Fe}(\text{CN})_6]_2$  with and without Pd had high bifunctional activity towards oxygen. It is believed that the original compound decomposes into mixed Ni/Fe hydroxides in the alkaline electrolyte which may co-catalyze each other in a similar way to the mixed Ni/Fe oxides [3].

The presentation also includes some preliminary results of the bifunctional electrode when coupled with an iron electrode and the design characteristics of the iron-air battery used.

Figure 1

Electrochemical Advanced Oxidation Processes (EAOPs) are promising technologies for the decontamination of wastewaters polluted with persistent organic products (POPs). The principal environmental problems of POPs involve the visual contamination, carcinogenic effects, toxicity, and other noxious effects even at low concentration. Indirect electrochemical processes based on Fenton's reaction have proved a fast and efficient removal of several pollutants from lab-scale up to pre-pilot plant scale (see Fig. 1 and 2).

In this work, we present an overview of electrochemical processes based on Fenton's reaction and their potentialities and weaknesses as environmental friendly technologies to depollute industrial wastewaters containing POPs. The basis and principles of these technologies will be described making a special emphasis on the advances in the last decade. Starting from the conventional electro-Fenton and finishing with the systems involving photocatalytic and photochemical reactions to enhance the mineralization efficiency. The new challenges on the field will be raised, highlighting topics such as the costs and the use of renewable sources of energy.

# Development of Lithium Recovery Technique from Seawater by using Innovative Electrodialysis with Lithium Ionic Superconductor

Tsuyoshi Hoshino

Lithium (Li) is rapidly becoming a valuable commodity. As a means of addressing global warming, the world is increasingly turning to the use of Li-ion batteries in electric vehicles and as storage batteries in the home; therefore, there is a growing need for Li. Furthermore, as a fuel for fusion reactors, tritium is produced by the reaction of lithium with neutrons in a tritium-breeding material.

I have proposed a new method for Li recovery from seawater by electrodialysis using an organic membrane impregnated with the ionic liquid PP13-TFSI [1]. Only Li ions can significantly permeate this membrane and thus pass from the anode side to the cathode side. Because the other ions (Na, etc.) in seawater are much less capable of permeating the membranes, Li becomes selectively concentrated on the cathode side (Fig. 1). In the measurements of the ion concentration on the cathode side as a function of the duration of the applied dialysis voltage (2V), the Li concentration increased with time, reaching 5.94% after 2 h. The other ions in seawater did not permeate the membrane. With both ends of the impregnated membrane covered with a Nafion 324 overcoat to prevent outflow of the ionic liquid, the Li concentration increased to 22.2%.

Furthermore, I propose a method for recovering Li from seawater by using world-first dialysis, wherein Li only permeates from the negative electrode side to the positive electrode side through a Li ionic superconductor functioning as a Li separation membrane (LISM). Measurements of the Li ion concentration at the positive electrode side as a function of dialysis duration showed that the Li recovery ratio increased to approximately 7% after 72 h with no applied electric voltage, and an electrical power of 0.04 V and 0.1 mA was generated (Fig. 2). Moreover, other ions in the seawater did not permeate the LISM. With both ends of the LISM bound with a negative and positive electrode, hydrated Li ion was transformed to Li ion only because Li ion can permeate through the LISM [2].

This new recovery method shows good energy efficiency and is easily scalable and is thus suitable for the industrialized mass production of Li in South American countries, which have briny water containing Li.

# Comparative Degradation of *trans*-Cinnamic and *trans*-Ferulic Acids by Electrochemical Advanced Oxidation Processes

Nelly Flores, Pere L. Cabot, Francesc Centellas, José Antonio Garrido, Rosa M. Rodríguez, Enric Brillas, Ignasi Sirés

Laboratori d'Electroquímica dels Materials i del Medi Ambient, Departament de Química Física, Facultat de Química, Universitat de Barcelona, Martí I Franquès 1-11, 08028 Barcelona, Spain  
e-mail address: nellyflorestapia@gmail.com

*Trans*-cinnamic acid ((E)-3-phenylprop-2-enoic acid) and *trans*-ferulic acid ((E)-3-(4-hydroxy-3-methoxyphenyl)prop-2-enoic acid) are main components in olive oil mill wastewaters [1]. In the last decades, electrochemical advanced oxidation processes (EAOPs) based on the electrogeneration of strongly oxidizing  $\bullet\text{OH}$  radicals have shown promising results for the remediation of wastewaters [2]. This communication presents a comparative study on the degradation of *trans*-cinnamic and *trans*-ferulic acids in acidic media by different EAOPs such as electrochemical oxidation with electrogenerated hydrogen peroxide (EO- $\text{H}_2\text{O}_2$ ), electro-Fenton (EF) and photoelectro-Fenton (PEF).

Electrolyses were carried out with a stirred tank reactor of 100 cm<sup>3</sup> equipped with a 3 cm<sup>2</sup> boron-doped diamond (BDD) anode and a 3 cm<sup>2</sup> carbon-polytetrafluoroethylene air-diffusion cathode for continuous  $\text{H}_2\text{O}_2$  generation. Synthetic aqueous solutions with 100 mg dm<sup>-3</sup> of total organic carbon (TOC) of *trans*-cinnamic or *trans*-ferulic acid in 0.05 mol dm<sup>-3</sup>  $\text{Na}_2\text{SO}_4$  at pH 3.0 were degraded by applying a current density between 16.7 and 100 mA cm<sup>-2</sup> for 360 min. In the EF and PEF experiments, 0.50 mmol dm<sup>-3</sup>  $\text{Fe}^{2+}$  was added as catalyst of Fenton's reaction, whereas in PEF, the solution was irradiated with a 6 W UVA lamp of  $\lambda_{\text{max}} = 360$  nm.

It was found that the solutions of both acids were mineralized at analogous rate for each procedure at given current density. The oxidation ability of EAOPs tested increased in the sequence  $\text{EO-H}_2\text{O}_2 < \text{EF} < \text{PEF}$ . At the end of the treatments at 33.3 mA cm<sup>-2</sup>, for example, TOC reductions of 68%, 78% and 98% for *trans*-cinnamic acid and of 61%, 79% and 96% for *trans*-ferulic acid, respectively, were obtained. An almost total mineralization was only reached by PEF, the most powerful EAOP in both cases. The increase in current density enhanced the mineralization rate for all the treatments due to the larger production of  $\bullet\text{OH}$  radicals from the acceleration of water oxidation at the BDD surface and in EF and PEF, of Fenton's reaction as a consequence of the greater generation of  $\text{H}_2\text{O}_2$  at the air-diffusion cathode. Thus, after 120 min of PEF process, TOC was reduced by 64% at 16.7 mA cm<sup>-2</sup> and much more rapidly up to 82% at 100 mA cm<sup>-2</sup> for *trans*-cinnamic acid, whereas it was removed from 74% to 81% when the current density varied from 33.3 to 100 mA cm<sup>-2</sup> for *trans*-ferulic acid. The decay of both acids obeyed a pseudo-first-order reaction, as determined by reversed-phase HPLC. They disappeared after about 360 min of EO- $\text{H}_2\text{O}_2$ , only needing between 10 and 35 min for EF and PEF. The much rapid decay in the two latter processes indicates that  $\bullet\text{OH}$  radicals formed from Fenton's reaction can destroy much more quickly both acids than those produced at the BDD anode. Short-linear aliphatic carboxylic acids were quantified by ion-exclusion HPLC. Oxalic acid was always the final product more largely generated. It was slowly and continuously accumulated in EO- $\text{H}_2\text{O}_2$  because of the slow destruction of precedent products by  $\bullet\text{OH}$  radicals formed at the BDD surface. The Fe(III)-oxalate complexes produced in EF and PEF were slowly removed under the action of  $\bullet\text{OH}$ , but completely photodecarboxylated to  $\text{CO}_2$  upon UVA irradiation. The quicker disappearance of oxalic acid by PEF then explains that this procedure is the most powerful EAOP for the remediation of acidic solutions of *trans*-cinnamic and *trans*-ferulic acids.

# Towards a More Competitive Advanced Electrochemical Technology: New Carbon-Based Electrodes Combination for Wastewater Treatment

Emmanuel Mousset, Zuxin Wang, Olivier P. Lefebvre

Centre for Water Research, Department of Civil and Environmental Engineering, National University of Singapore,

1 Engineering Dr. 2, Singapore 117576, Singapore

*ceeem@nus.edu.sg*

The release of hazardous persistent organic pollutants (POPs) into the environment is a common concern since they can be detected in low amounts in rivers, lakes, oceans, and even drinking water all over the world. Since these pollutants cannot be significantly removed in conventional wastewater treatment plants current interest is focusing on the development of simple, safe, effective, and economical physico-chemical technologies for the total removal of POPs. Electrochemical advanced oxidation processes (EAOPs) producing electrochemically high oxidizing species like  $\cdot\text{OH}$  are particularly promising [1]. Among them electro-Fenton has emerged because of its many advantages including  $\text{H}_2\text{O}_2$  electro-generation and  $\text{Fe}^{2+}$  electro-regeneration at the cathode avoiding the addition of chemicals and the production of sludge. It can also achieve very high degradation and mineralization rates of numerous organic pollutants [2]. To increase the cost-effectiveness of the process, it is important to develop novel and more cost-effective electrode materials.

In this context, new cathode materials consisting of carbon cloth and carbon fibers shaped as a brush or as a wire have been tested in the electro-Fenton (EF) process and compared to more conventional electrode materials (graphite, carbon felt and boron-doped diamond (BDD) and Platinum (Pt)). To select the best cathode, the performance of these electrodes was evaluated with a number of parameters, including maximal  $\text{H}_2\text{O}_2$  concentration, specific surface area, current efficiency, applied charge, energy consumption and material cost. The multi-criteria approach concluded that the carbon fiber brush outcompeted all other cathodes, especially in terms of  $\text{H}_2\text{O}_2$  production (Fig. 1a). This performance was attributed to the high specific surface area of the brush and was successfully explained by a modeling approach. This cathode was then used for studies performed with different anode materials. The influence of the different electrode combination on the degradation and mineralization kinetics (phenol) was carried out. A major finding was that carbon cloth material performed comparably to a more expensive Pt anode (Fig. 1b). In conclusion, the combination of carbon fiber brush cathode and carbon cloth anode gave promising performance, especially in consideration of process upscaling issues.

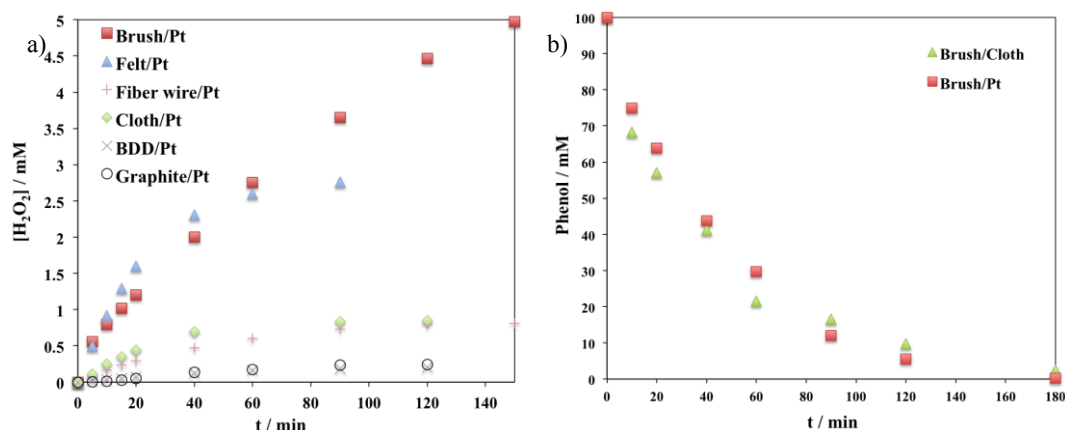

Figure 1a) Performance of carbon fiber brush cathode vs. other materials; b) performance of carbon fiber brush cathode combined with carbon cloth anode vs. Platinum.

# **Abatement of pollutants in water by different electrochemical approaches**

Onofrio Scialdone, Adriana D'Angelo, Simona Sabatino, Alessandro Galia  
*Università degli Studi di Palermo*  
*Viale delle Scienze, 90100 Palermo*  
*onofrio.scialdone@unipa.it*

Electrochemical based technologies are very promising methods for treating wastewaters containing organic and inorganic pollutants resistant to biological processes or toxic for microorganisms. These methods present numerous advantages including the utilization of a green reagent such as the electron, very high removal of numerous recalcitrant pollutants, efficient disinfection, high flexibility and no necessity to transport or stock chemical oxidants or reductants. On the other hand, a wide utilization of such methods is likely to be limited by: (i) the cost of electric energy necessary to drive electrode reactions; (ii) the cost of the supporting electrolyte for waste waters with no adequate conductivity and (iii), for some applications, by the cost of electrodic materials.

To avoid the supply of electric energy to the system, various solutions were proposed including the utilization of microbial fuel cells, reverse electrodialysis or microbial reverse electrodialysis processes, while the utilization of microfluidic apparatuses can allow to work with wastewater with low conductivity.

The potential utilization of these kinds of apparatuses (microbial fuel cells, reverse electrodialysis, microbial reverse electrodialysis, microfluidic cells) for the treatment of wastewater will be discussed.

# On the necessity of field studies for direct electrochemical drinking water disinfection

M.E.H. Bergmann<sup>1</sup>, W. Schmidt<sup>2</sup>, J. Hartmann<sup>1</sup>

Anhalt University, Köthen, Bernburger Str. 55, D-06366 Köthen/Anh., Germany

<sup>2</sup>TZW Dresden, Wasserwerkstraße 2, 01326 Dresden

[h.bergmann@emw.hs-anhalt.de](mailto:h.bergmann@emw.hs-anhalt.de)

Direct electrochemical drinking water disinfection in flow-through cells, the so-called *Inline Electrolysis* (IL), is a well-known but poorly understood process for water hygienization. This is the reason, why the method is to this day not allowed for legal application in Germany, albeit it is used in many other countries. To close the knowledge gap, water authorities, research centers and companies producing electrochemical disinfection cells have completed a joint project on IL. The main goal was to identify conditions of safe cell exploitation, i.e. conditions of satisfying disinfectant production on the one hand, and minimized by-product formation on the other hand. Several electrode materials (mixed oxide coatings and boron doped diamond) and different technical cells were studied with respect to their chlorine production and by-product formation. Amongst others, chlorate, perchlorate, bromate, THM [1] and AOX were the by-products of increased interest. Current density was varied between 10 and 571 A m<sup>-2</sup> mostly at temperatures between 15 °C and 30 °C over all experiments. Natural waters with and without chloride addition, and artificial waters were tested.

Results revealed significant differences in chlorine production due to different activities of anode materials used by cell producers. Electrolysis at chloride concentration between 20 and 250 mg dm<sup>-3</sup> conducted in laboratory cells with mixed metal oxide anodes was safe with respect to chlorate and perchlorate formation when the mode of applied current according to own rules of cell producers was respected. Chlorate was only found in studies with one electrode material. Usually, bromide concentration should not be higher than 1 mg dm<sup>-3</sup> to avoid bromate formation. Doped diamond electrodes showed still unacceptable chlorate and perchlorate formation. In contrast to lab-scale experiments, field studies at technical scale showed chlorate formation for all mixed oxide anode materials. Non-optimized cell constructions are responsible for this behavior. Perchlorate was only detected in technical cells using diamond doped electrodes.

The formation of organic by-products in waters free of bromide was comparable to chemical chlorination of drinking waters, when for example THM concentration is not allowed to be higher than 50 µg dm<sup>-3</sup>.

Results can be interpreted as a step toward legal application of IL. New criterions were defined for better discussion of results from laboratory-scale experiments [2]. Results are currently used to discuss new limiting concentration that is not yet clearly defined for chlorate and perchlorate in drinking water. It seems to be necessary to define test routines for technical electrolyzers. Model water systems were defined for this purpose.

# **Sustainable Electrolysis for Electrowinning and Electrorefining of Metals in Molten Salts and Aqueous Electrolytes**

Geir Martin Haarberg and Junli Xu

*Department of Materials Science and Engineering, Norwegian University of Science and Technology,*

*NO-7491 Trondheim Norway*

[geir.martin.haarberg@ntnu.no](mailto:geir.martin.haarberg@ntnu.no)

Fundamental laboratory studies can provide possibilities for developing sustainable electrolysis processes for metal deposition in terms of energy and environment. Laboratory experiments were carried out to study electrodeposition of iron from molten salts and aqueous solutions using an inert oxygen evolving anode to eliminate the emissions of CO<sub>2</sub>. The possibilities of molten salt electrorefining of metallurgical grade silicon to produce solar grade silicon were also investigated. Electrochemical techniques were used to study the electrochemical behaviour of dissolved iron, silicon, and titanium species. Bulk electrolysis was carried out to deposit pure iron, silicon, and titanium. The deposits were characterized by SEM/EDS and XRD analyses. Calculations based on laboratory studies indicate that great improvements in terms of reduced energy consumption and CO<sub>2</sub> emissions can be achieved by successful implementation of new technologies. Electrolysis may also play an important part in recycling of waste to recover the metal value. Electrodeposition of lead, indium and tin was studied in molten chloride electrolytes.

# Electrocatalytic properties of Cu-/Ni-loaded nanoporous carbons for the electrooxidation of alcohols

Leticia García-Cruz<sup>1</sup>, Vicente Montiel<sup>1</sup>, Conchi O. Ania<sup>2</sup>, Jesús Iniesta<sup>1\*</sup>

<sup>1</sup> Dept. Química Física e Instituto de Electroquímica, Universidad de Alicante, E-03080 Alicante, Spain.

jesus.iniesta@ua.es

Nanoparticulated systems incorporating non-precious metals are gaining much interest as a replacement of low performing and high cost noble metals in different research fields such as electroanalysis, electrocatalysis, fuel cells and electrosynthesis, among others. Copper has a rich redox chemistry, with many oxidative reactions being catalyzed by different copper complexes and oxides. However, copper species easily undergo corrosion under certain electrolytes for which an important issue to improve the performance of copper-based materials is to control the size, shape, composition, structure and dispersion of the metallic nanoparticles. Similarly, the electrocatalytic properties of nickel hydroxide/oxyhydroxide -Ni(OH)<sub>2</sub>/NiOOH- electrodes for the electro-oxidation of unsaturated alcohols (i.e., alken-1-ols or alkyn-1-ols) in alkaline medium have also been explored. Despite the excellent results concerning stereoselectivity and conversion yields, there are still important limitations related to the deactivation of nickel electrode surface and the formation of inactive species during long cycling electrooxidative runs [1,2].

To this end, a series of nickel and copper-doped nanoporous carbons were prepared using various precursors (coal, lignocellulose and organic polymers) and synthetic routes [3,4]. Initially, the electrochemical response of the prepared materials towards the electrooxidation of alcohols was investigated, correlating the electrocatalytic activity with the characteristics of the electrode materials (porosity, surface chemistry of the nanoporous carbon, copper and nickel loading and dispersion), and the type and concentration of the alcohol molecule. The best performing metal-doped nanoporous carbon electrodes were selected for the preparation of copper/carbon and nickel/carbon films. To do that, several catalytic inks were prepared and deposited onto carbon cloth (Toray Paper) by using airbrushing technique. The different doped carbon electrodes with nickel and copper were characterized by SEM, TEM, XPS and electrochemical techniques such as cyclic voltammetry. The electrooxidation of small organic alcohols, e.g. propargyl alcohol PGA was performed to look into nickel and copper catalytic properties in addition to study how the carbon matrix influences on the final product of alcohol electrooxidation.

Preparative electrolyses in alkaline conditions at either controlled potential or current intensity were carried out to assess the electrocatalytic activity of copper nanoparticles and carbon matrix affects on the final oxidation products. Furthermore, the feasibility of the scale up of the process was also evaluated using a polymer electrolyte membrane electrochemical reactor (PEMER), as well as the feasibility of the Cu and Ni-doped nanoporous carbons as electrodes in direct alcohol fuel cells under alkaline conditions.

To build a hydrogen-based society, it is imperative to establish a large-scale hydrogen supply system. Organic chemical hydrides have been drawing attention as hydrogen carriers because they are liquid at ambient temperature and pressure. Recently, Chiyoda Corporation has verified a large-scale hydrogen storage and transportation system by using an organic chemical hydride technology, involving catalytic hydrogenation of toluene forming methylcyclohexane (MCH) and dehydrogenation of MCH [1].

From viewpoints of effective use of electricity from renewable sources and energy conversion efficiency, direct electrochemical hydrogenation (DEH) of toluene is preferable to fix hydrogen. So far, there have been several studies of the DHE of toluene by applying a membrane electrode assembly (MEA) consisting on a polymer electrolyte and Pt-based nanoparticle electrodes [2]. However, it is open to question whether the MEA technique is best suited to the DEH of liquid aromatic organics since MEAs have originally been developed for fuel cells in which reactants are gaseous.

In a bicontinuous microemulsion (BME), electrochemical contact with micro aqueous and organic solution phases can be simultaneously achieved by controlling hydrophilicity and lipophilicity on an electrode surface [3]. In the present study, we have, for the first time, applied a BME technique, instead of MEA, to the DEH of toluene, and successfully obtained a significant reduction current at a Pt electrode in a BME solution.

The BME solution was prepared from toluene, a  $\text{H}_2\text{SO}_4$  solution and surfactants (sodium 1-dodecanesulfonate and a co-surfactant). A mirror-finished polycrystalline Pt electrode and a reversible hydrogen electrode (RHE) were employed as working electrode and reference electrode, respectively.

Fig. 1 shows cyclic voltammograms (CVs) of the Pt electrode in  $\text{H}_2\text{SO}_4$  with / without the surfactants and in the BME solution. In the  $\text{H}_2\text{SO}_4$  solution, the Pt electrode exhibited a characteristic reversible hydrogen adsorption wave below 400 mV. However, it was found that the surfactants hindered the hydrogen adsorption due to an adsorption of surfactants on the Pt surface. In the BME solution, it should be pointed out that a large reduction current was raised at a more positive potential than the hydrogen evolution reaction (HER). Fig. 2 shows steady-state polarization curves in these solutions. It is clearly seen that the reduction currents in the BME solution are significantly larger than those in the other solutions in the whole potential region between 0 and 100 mV.

This preliminary result indicates that the BME technique, much simpler and cheaper than the MEA technique, has a great potential for the DEH of liquid aromatic organics.

One of the most interesting processes for hydrogen production is the steam reforming of alcohols by using catalysts such as Cu, Pt, Pd or Ni supported on metal oxides such as ZnO or CeO<sub>2</sub>. On the other hand, many efforts are devoted to finding safe and efficient systems for H<sub>2</sub> transport and storage [1]. The use of ionically conducting materials (e.g., K-βAl<sub>2</sub>O<sub>3</sub>) as electroactive catalyst supports has shown to be an useful tool for in-situ activating Pt-based catalysts in the methanol steam reforming reaction by the electrochemical migration of promoter ions (e.g., K<sup>+</sup> ions) [2]. In the present work, the controlled production, storage and release of H<sub>2</sub> have been studied on novel Ni catalysts with very high porosity (Figure 1a), prepared by the oblique-angle deposition method. As can be observed in Figure 1b, under steam reforming conditions, the application of a negative electric current or potential and the consequent migration of K<sup>+</sup> ions from the K-βAl<sub>2</sub>O<sub>3</sub> to the Ni surface favored the dissociative adsorption of methanol and the formation of carbon surface compounds. Subsequently, in inert atmosphere, a positive polarization led to the decomposition of these compounds and the release of H<sub>2</sub>, CO<sub>2</sub> and CO. Hence, this electrocatalytic system showed a great practical interest for the simultaneous production and storage of hydrogen (up to more than 15 g H<sub>2</sub>/100 g Ni) and its in-situ release in a controlled and reversible way.

**Figure 1.** SEM images of a highly porous Ni catalyst film prepared by oblique-angle deposition (a). Controlled production and release of H<sub>2</sub>, CO and CO<sub>2</sub> by application of an electric current or potential (b).

# Graphene-based electrodes: a new promising material for a more competitive electro-Fenton technology

Emmanuel Mousset, Muhammad Syafiq Bin Ahmad, Zuxin Wang, Olivier Lefebvre  
Centre for Water Research, Department of Civil and Environmental Engineering, National University of Singapore,  
1 Engineering Dr. 2, Singapore 117576, Singapore  
*ceelop@nus.edu.sg*

Electrochemical advanced oxidation processes (EAOPs) are being developed in order to treat the hazardous persistent organic pollutants (POP) that are being released into the environment, especially in water. These methods are based on the electrochemical generation of a very powerful oxidizing agent, in the form of the hydroxyl radical ( $\cdot\text{OH}$ ), which can mineralize and therefore destroy organics. Among these processes, electro-Fenton, based on the Fenton's reagent ( $\text{H}_2\text{O}_2$  and  $\text{Fe}^{2+}$ ) electro-(re)generation, has emerged for its many advantages, including no chemical addition, no sludge production and very high organic pollutant mineralization rates [1].

The electrode material is the key parameter that determines the effectiveness of the process and therefore effort have been directed towards the development of novel cost-effective materials, such as carbon-based electrodes. Among them, graphene material is becoming very popular. Its exceptional properties, including electronic and thermal conductivities have triggered a graphene gold rush; however the potential of graphene as an electrode material for environmental applications is only starting to be considered [2].

In this context, this study discusses first the production of a graphene electrode through a cost-effective method and second its performance evaluation in the electro-Fenton process. In order to make graphene-based electrodes, graphene was first synthesized through two distinct pathways: chemical method and electrochemical exfoliation. The latter gave better performance not only regarding the quality of the graphene obtained as determined by transmission electron microscopy (Fig. 1a) but also in terms of chemical requirement, equipment requirement and reproducibility. Therefore, this method was selected to elaborate a graphene-based electrode by using the ink-coating technique on carbon cloth. The electrode was characterized by cyclic voltammetry and then used as cathode for electro-Fenton.  $\text{H}_2\text{O}_2$  production was monitored over time to evaluate the performance of the graphene-based electrode. The graphene-coated cloth was able to produce twice as much  $\text{H}_2\text{O}_2$  as the uncoated one (Fig. 1b), demonstrating the role of graphene to enhance process efficiency. The presentation will include data on degradation of several micro-pollutants and a technico-economical discussion of the potential environmental applications for the technology.

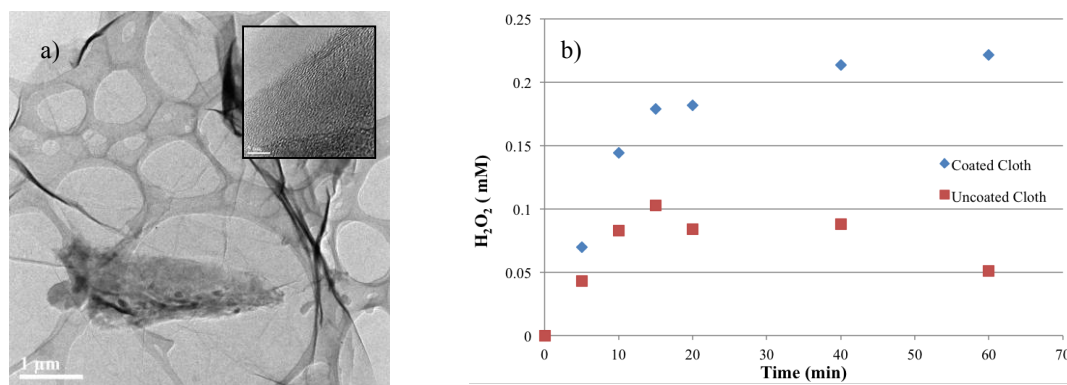

Figure 1a. TEM pictures of graphene sheet produced with electrochemical exfoliation (insert: lattice on the edge of the sheet); b) Comparison between graphene-coated cloth vs. uncoated cloth for  $\text{H}_2\text{O}_2$  electro-generation performance.

The cogeneration of electricity and valuable chemicals in a fuel cell is an emerging field of research in the context of sustainability [1]. An interesting example thereof is the cogeneration of electricity and aniline in a  $\text{H}_2/\text{PhNO}_2$  fuel cell [1,2]. This process allows the conversion of nitrobenzene into aniline, which is an important reagent used in industry for the synthesis of methylene diphenyl diisocyanate, a precursor in the production of polyurethane. The development of a suitable electrocatalyst is of crucial relevance for achieving high current and selectivity towards hydroxylamine in a  $\text{H}_2/\text{PhNO}_2$  fuel cell.

Here, we present novel electrocatalysts for the conversion of nitrobenzene to aniline, based on N-doped graphitic carbon materials prepared by controlled pyrolysis of polyaniline containing non-noble metal centers [3]. These materials display important assets: (1) metals with at least two accessible oxidation states to successfully adsorb aniline and initiate its reduction; (2) the extended delocalized  $\pi$ -system of the N-doped carbon granting good electrical conductivity.

The polyaniline-based electrocatalysts were synthesized by varying the type and loading of metal species (Fe, Cu and Co) and the pyrolysis temperature, and by studying the effect of the extent of acid leaching to remove inactive metal species. The performance of these electrocatalysts in the reduction of nitrobenzene was evaluated by means of linear sweep voltammetry (LSV) in a half cell containing 5 mM nitrobenzene in 0.3 M  $\text{HClO}_4$  in ethanol.

The nature of the metal center, its final content and the pyrolysis temperature proved to strongly affect the electrocatalyst performance in terms of onset potential and current densities. The performance of the electrocatalysts in the nitrobenzene reduction enhanced from Fe to Cu to Co (see Fig. 1 A). In general, the performance improved by increasing the metal loadings. The optimal activity in the reduction of nitrobenzene was reached with the materials pyrolysed at 900°C (see Fig. 1 B). By means of the Koutecký-Levich equations, it was determined that the amount of exchanged electrons ( $n$ ) was close to 6 at -0.75 V for the Co- and Cu-based electrocatalysts, indicating a selective production of the desired aniline. This represents a relevant improvement compared to the most promising electrocatalysts reported in the literature for this reaction (Cu/MWCNTs ( $n = 4$  at -0.75V) [1,2]. These results highlight the potential of our novel noble-metal-free electrocatalysts for the reduction of nitrobenzene to aniline in a fuel cell setup with the cogeneration of electricity.

Electro-disinfection processes are gaining increasing attention because of their simple control, easiness of operation and effectiveness, being widely used in applications such as the disinfection of swimming pools and becoming a very promising alternative in the reclaiming of treated wastewater. Combination of disinfection with electrodialysis could be of interest in these processes, in particular when reclaimed wastewater is to be used in irrigation, because of the high standards required to the outcoming low-salinity stream in order to prevent diseases.

In the present work, novel anionic and cationic composite membranes are developed and tested for this purpose. These membranes contain microparticles of different materials, added with the purpose of behaving as bipolar electrodes and hence of promoting the production of disinfection reagents in the different compartments of the electrochemical cell.

Results obtained depends largely on the type of microparticles added ( $\text{TiO}_2$  and  $\text{RuO}_2$ ) and they demonstrate that hypochlorite can be effectively produced in the compartments placed in both sides of the membranes, demonstrating that microparticles behave as effective bipolar electrodes (Figure 1). Disinfection tests are used as proof of concept and they confirm the feasibility of these processes. Characterization of the new membranes is also assessed in this work.

[pg-ochiai@newkast.or.jp](mailto:pg-ochiai@newkast.or.jp)

You might have experienced... when the cavity has reached the pulp, we have to ask for a dentist to remove dead and infected material away from a root canal of the tooth with dental instruments, and then sterilize the root canal by NaClO. This is conventional “root-canal therapy”. However, sometime remaining bacteria can lead to not only periapical periodontitis but also serious health issues. Recently, we have reported a pinpoint electrolysis unit with BDD microelectrode and its great potential for dental treatments such as sterilization of root-canal [1]. However, inflexible polycrystalline BDD film peeled off from the substrates easily. In this study, we devise flexible pinpoint electrolysis unit by using of BDDP-based polymer composite for dental treatment.

The unit was prepared as shown in Figure 1. A metal wire surface was coated by BDDP-based polymer composite consist of BDDP [2] and 20% Nafion<sup>®</sup> dispersion solution at a specified mixing ratio as an anode. A Pt-ribbon with ion-exchange membrane was spirally wound around the metal wire's surface as a cathode. When DC voltage is applied between the anode and the cathode in the water, ozone and oxidative intermediates are generated. The unit showed almost the same sterilization ability as 1 wt% of aqueous NaClO treatment in *in vitro* assessment in the root-canal of human teeth. Moreover, the BDDP-based polymer composite has excellent durability which hardly causes cracks and peeling off even by repeated bending during the electrolysis. The superiority of BDDP-based polymer composite over simple and easy-to-handle pinpoint electrolysis unit, in terms of the flexibility, durability, and disinfection activity was demonstrated with the conventional methods and conditions. This research is attractive to develop a practical unit for dental treatment.

**Figure 1.** Schematic image of the flexible pinpoint electrolysis unit with BDDP-based polymer composites and its preparation.

and Emmanuel Iwuoha

*SensorLab, Department of Chemistry, University of the Western Cape, PB X17, Bellville 7535, South  
Africa; [pbaker@uwc.ac.za](mailto:pbaker@uwc.ac.za)*

PAHs are widely distributed in the atmosphere, soils, sediments and ground water as well as marine sediments. Emissions of PAHs into the air can be transported over long distances before deposition into soils, vegetation, sea or inland waters occur via atmospheric precipitation. Due to the low solubility of PAHs in aqueous media as well as their strong hydrophobic nature, these PAHs contaminants associate with particulate material in the aquatic environment with underlying sediments as their ultimate sink. High performance liquid chromatography (HPLC) is the standard method employed for the determination of the 16 priority PAHs identified by World Health Organisation (WHO). Various electrochemical methods have been used for the screening and detection of these PAHs contaminants. However, HPLC methods have a number of disadvantages associated with the method i.e. isomeric PAH peaks which partially overlap, preparation of the samples is time consuming due and matrix interferences complicate efficient measurement and quantification.

SensorLab researcher have developed many viable sensor systems for screening and quantification of the WHO priority PAHs including anthracene, naphthalene, fluoranthene, chrysene, acenaphthylene, benzo[b]fluoranthene and triphenylene. The electrochemical methods employed for the detection of these PAHs include electrochemical quartz crystal microbalance for naphthalene and fluoranthene, based on luciferase inhibition(1), voltammetric evaluation of anthracene oxidation at Ag-Au Alloy nanoparticles/overoxidized-polypyrrole composite(2) and square wave voltammetry analysis of chrysene, acenaphthylene, benzo[b]fluoranthene and triphenylene at poly(phenazine-2,3-diimino(pyrrole-2-yl) electroactive actuator. This paper will concentrate on the selectivity and specificity criteria for detection of PAHs in samples of mixed composition, towards development of a multi-array sensor ensemble for reliable and cost effective electrochemical screening method for priority polycyclic aromatic hydrocarbons.

# Electrochemical Processes for Green Environment: the emerging technology in wastewater treatment

Bahadır K. Körbahti

Mersin University

Faculty of Engineering, Chemical Engineering Dept., Çiftlikköy 33343 Mersin, Turkey

korkbahti@mersin.edu.tr, korkbahti@gmail.com

Electrochemical processes for wastewater treatment have been attracted great attention in recent years. The oxidation of organic pollutants in wastewater could be accomplished by direct and indirect electrochemical mechanisms (Figure 1). In direct oxidation, organic pollutants are oxidized after adsorption on the anode surface with the involvement of the electron, which depends on the electrocatalytic activity of anode material. Although direct anodic oxidation is capable of removing organic pollutants from wastewater, direct oxidation reactions of organics on inert anodes are very slow due to reaction kinetics and limiting reactions. Therefore, most electrochemical methods are based on indirect electrolysis in which the organic pollutant is removed in the solution by active species produced in a reversible or an irreversible process, and the redox reagent can be electrogenerated by either anodic or cathodic process.

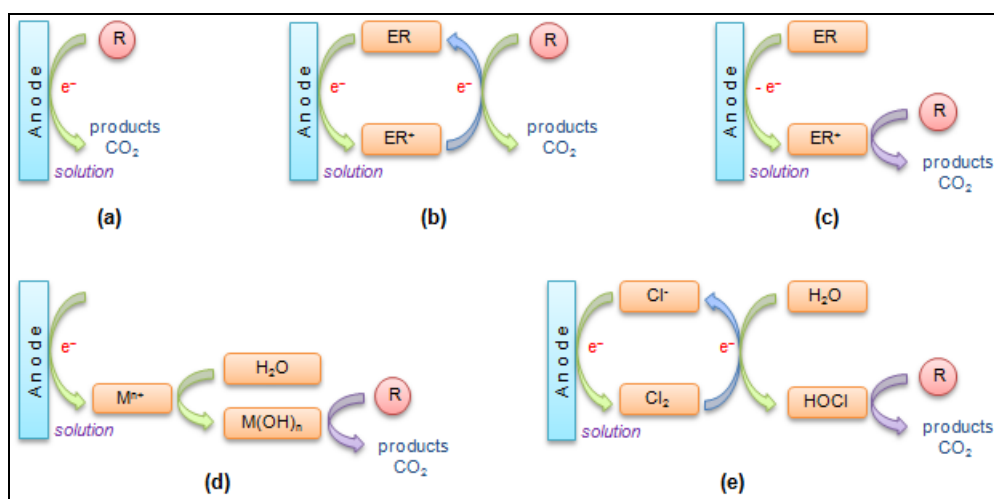

Figure 1. Mechanisms for the electrochemical oxidation of organic pollutants: (a) direct oxidation, (b)-(c) indirect oxidation by electrogenerated oxidizing reagent (ER), (d) indirect oxidation by metal hydroxides, (e) indirect oxidation by active chlorine.

In our research group, electrooxidation, electroreduction, electrodeposition, electrocoagulation, and electroflotation processes by direct and indirect mechanisms (Figure 1) have been investigated for the electrochemical abatement of phenols, pharmaceuticals, textile dyes, bilge water, paint industry wastewater, domestic wastewater, and removal of heavy metal ions using boron-doped diamond (BDD), platinum/iridium, platinum, stainless steel, iron, and graphite electrodes in electrochemical reactors of batch and continuous operating modes. It is possible to obtain complete oxidation of organic pollutants to  $\text{CO}_2$  or partial oxidation to intermediate compounds according to the process conditions. In our studies, we aimed to identify possible underlying phenomena of chemical reaction kinetics and mass transfer in electrochemical processes. It has been found that reaction order, activation energy, mass transfer coefficient, and energy consumption depend on the nature of the anode, hydrodynamic conditions, electrolyte type, applied current density, and pollutant concentration.

# Role of Sulfate and Persulfate Ions in Electrochemical Oxidation of Persistent Organics at a Boron-doped Diamond Anode

Ali Farhat<sup>a</sup>, Stephan Tait<sup>a</sup>, Jurg Keller<sup>a</sup>, Jelena Radjenovic<sup>a,b</sup>

<sup>a</sup> Advanced Water Management Centre, The University of Queensland, Queensland 4072, Australia

<sup>b</sup> Catalan Institute for Water Research (ICRA), Scientific and Technological Park of the University of Girona, 17003 Girona, Spain  
e-mail: a.farhat@awmc.uq.edu.au

The incomplete removal of persistent organic compounds such as pharmaceuticals and pesticides in conventional water and wastewater treatment plants have raised the interest for novel technologies capable of effectively degrading such organic contaminants. Electrochemical advanced oxidation processes (EAOPs) employing boron doped diamond (BDD) anodes have been previously reported to accomplish significant degradation of such trace organic contaminants. Previous studies have shown that BDD anodes are characterized with high overpotential for oxygen evolution where such anodes enhance the degradation rates of organics via direct oxidation and production of weakly adsorbed hydroxyl radicals (HO<sup>•</sup>). Besides HO<sup>•</sup> and other radical species, BDD anodes can also produce peroxy-species that may also contribute to bulk oxidation of contaminants. For example, previous research has reported BDD anodes are capable of oxidizing sulfate ions to peroxydisulfate (S<sub>2</sub>O<sub>8</sub><sup>2-</sup>), via sulfate radicals (SO<sub>4</sub><sup>•-</sup>) as intermediate products.

To further explore the role of sulfate in EAOPs, the present study quantified the rates of electrooxidation of several persistent organic contaminants (e.g., diatrizoate, carbamazepine, N,N-diethyl-meta-toluamide (DEET), iopromide, tribromophenol, triclosan and triclopyr) at BDD anode. Experiments were performed in sulfate anolyte at different operating conditions (concentrations/conductivities and current densities) and compared with inert nitrate and perchlorate anolytes. The observed electrooxidation rates of the persistent organic contaminants in sulfate anolyte were in the range of 12 – 66 h<sup>-1</sup>, significantly higher than the values obtained for nitrate anolyte (0.83 – 5.4 h<sup>-1</sup>).

Given that in the absence of trace metals or other activators (e.g., UV light), persulfate was shown to exhibit slow oxidation kinetics with these persistent organic contaminants (k < 0.1 h<sup>-1</sup>), higher electrooxidation rates in the presence of sulfate were assigned to the electrochemical activation of sulfate ions to sulfate-based oxidizing species such as sulfate radicals (SO<sub>4</sub><sup>•-</sup>) and/or non-radically activated persulfate. In an attempt to segregate the effects of HO<sup>•</sup> radicals and SO<sub>4</sub><sup>•-</sup> radicals, the study also examined the electrooxidation of nitrobenzene at a BDD anode, as a typical HO<sup>•</sup> radical probe compound, and provided further evidence for the presence of SO<sub>4</sub><sup>•-</sup> radicals.

Sulfate-based solutions have been widely used as supporting electrolytes for electrochemical degradation of contaminants using BDD anode. Electrooxidation pathways have been largely explained by the role of HO<sup>•</sup> radicals and other reactive oxygen species. Our results imply electrochemical activation of sulfate ions, even at sulfate concentrations as low as 150 mg L<sup>-1</sup>. Thus, this study has implications in applications of BDD anodes in wastewater treatment, as the presence of sulfate may significantly affect the electrooxidation pathways and kinetics of persistent organic contaminants.

# Fluoride Removal from Drinking Water by Electrocoagulation in a Continuous Filter Press Reactor coupled to a Flocculator and Clarifier

\*ma.sandovallopez@ugto.mx

The problems related to water scarcity in Mexico and many regions in the world are due to geographical location, low rainfall and uncontrolled consumption. They have forced communities to use groundwater which contains fluoride concentrations above the maximum level recommended by the World Health Organization ( $1.5 \text{ mg L}^{-1}$ ). Fluoride pollution in the environment occurs through two different ways: natural sources and anthropogenic sources [1]. Recent studies performed in Mexico have demonstrated the presence of fluoride in Central and Northwestern regions with concentrations up to  $9.5 \text{ mg L}^{-1}$ . The level of fluoride in drinking water is an important factor in human health. It has both beneficial and harmful effects. It helps prevent teeth deterioration and dental caries but long-term consumption of water containing excess of fluoride ( $>4 \text{ mg L}^{-1}$ ) can lead to fluorosis of the teeth and bones [2]. The electrocoagulation (EC) has been considered as an alternative to remove fluoride in drinking water treatment because it lowers the amount of sludge and also provides some significant advantages such as, quite compact and easy operation, no chemical additives needed, and high flow rates [3].

Testing water for EC treatment was prepared from analytic reagents to obtain  $10 \text{ mg L}^{-1} \text{ F}^{-}$  in  $0.5 \text{ g L}^{-1} \text{ Na}_2\text{SO}_4$  and  $1.5 \text{ mg L}^{-1} \text{ NaClO}$  at  $\text{pH} = 7.7$ , giving an electrical conductivity of  $410 \mu\text{S cm}^{-1}$ . This solution resembles water from deep wells in Central region in Mexico. The system consists of a continuous filter press cell in which the coagulant is produced. The resulting solution (mixture of water and coagulant) is passed to a flocculator to induce flocculation of aluminum-fluoride flocs. Then, the solution is introduced to a clarifier, which is a sludge settler, to separate the sludge from the clarified water. The connection of current intensity supplied to the electrodes was in monopole configuration. Aluminum electrodes with 99.7% purity were used as anodes and cathodes. This reactor, coupled to a flocculation and clarification units, was developed in our laboratory. EC tests were performed with current densities of  $4\text{--}8 \text{ mA cm}^{-2}$  under different hydrodynamic conditions imposed by volumetric flow rates, comprised between  $0.1$  and  $0.4 \text{ L min}^{-1}$ . Fluoride was analyzed in the resulting clarified solution. After dissolution of the floc, aluminum was also analyzed. SEM, EDA-X and FTIR analyzes were performed.

Fig. 1 shows residual fluoride concentration as a function of mean linear flow rates in the EC reactor at a current density of  $6 \text{ mA cm}^{-2}$ . The experimental and theoretical aluminum doses are also shown. At  $0.91$  and  $1.82 \text{ cm s}^{-1}$ , we obtained the desired residual fluoride concentration ( $<1.5 \text{ mg L}^{-1}$ ).

Fig. 1. Influence of the mean linear flow rate on the residual fluoride concentration and aluminum dose for synthetic water at a current density of  $6 \text{ mA cm}^{-2}$ .

SEM experiments showed a  $69 \mu\text{m}$  amorphous floc. EDA-X ratified that the aluminum flocs entrap the fluoride. FTIR analysis suggested a  $\text{Al(OH)}_3\text{-F}_x$  reaction.

Ionic liquids (ILs) are one of the most promising quasi-solid-state (QSS) electrolytes for many electrochemical devices. However, traditional room temperature IL electrolytes exist in the liquid state. The fluidity and potential leakage of traditional IL electrolytes is still unavoidable, which limits their practical applications. Recently, the polymeric ILs have received growing attention as alternatives to the organic liquid electrolytes and traditional IL electrolytes since the unique properties of ILs are incorporated with the polymer. In this study, we synthesized a novel polymeric IL electrolyte for use in complementary electrochromic devices (ECDs).

With the evolution of nanotechnology, the nano-sized particles of Prussian blue analogues (PBA) have received wide attention in electrochromic devices (ECDs). Since the electrochemical growth of PBA thin film on a transparent conducting substrate has been a challenging task due to poor stability of the deposition bath which consisted of a metal salt and ferric cyanide, there is a tendency for the rapid co-precipitation after mixing. We first synthesized zinc hexacyanoferrate (ZnHCF) nanoparticles through surface modification using sodium ferrocyanide decahydrate, which benefits its uniformity and the dispersity. Furthermore, a uniform nano-structural ZnHCF thin film can be prepared by the spin-coating method, which is suitable for the large-scale production.

Subsequently, a new polymeric IL electrolyte (Fig. 1), namely poly(oxyethylene)-imide imidazolium perchlorate (POEI-ClO<sub>4</sub>), was prepared and investigated for QSS-ECDs. Herein, POEI-ClO<sub>4</sub> acts simultaneously as a charge-transfer mediator in the electrolyte and a polymer for the gelation of an organic solvent-based electrolyte; the complementary QSS-ECD is composited of a poly(3,3-diethyl-3,4-dihydro-2H-thieno-[3,4-b][1,4]dioxepine) (PProDOT-Et<sub>2</sub>) thin film, a ZnHCF thin film and the POEI-ClO<sub>4</sub> gel electrolyte. The thermal stability of the novel polymeric IL electrolyte, POEI-ClO<sub>4</sub>, was characterized by a thermogravimetric analyzer (TGA). The 5% weight loss temperature (Td<sub>5%</sub>) of the POEI-ClO<sub>4</sub> was 272 °C. The ECD using POEI-ClO<sub>4</sub> gel electrolyte was operated at the applied potentials of 1.5 V for bleaching and -1.8 V for coloring. As shown in Fig. 2, the pertinent QSS-ECDs exhibited a superior transmittance change ( $\Delta T$ ) of 56% at 590 nm. This newly designed polymeric IL, POEI-ClO<sub>4</sub>, provides a new material and great potential for realizing highly efficient QSS-ECDs.

Fig. 1 The chemical structure of POEI-ClO<sub>4</sub>.

Fig. 2 The transmittance response at 590 nm for the complementary ECD in response to the applied potentials of 1.5 and -1.8 V (ZnHCF vs. PProDOT-Et<sub>2</sub>).

A complementary electrochromic device (ECD), composed of anodically coloring poly(N',N'',N'''-tris[N,N-bis-(4'-diphenylamino-biphenyl-4-yl)phenyl]-1,3,5-benzene-tricarboxamide) (PG1) thin film and cathodically coloring poly(3,3-diethyl-3,4-dihydro-2H-thieno-[3,4-b][1,4]dioxepine) (PProDOT-Et<sub>2</sub>) thin film, has been fabricated. The proposed ECD exhibits sub-second scale switching time of less than 0.2 s and significant transmittance change of 53% at 590 nm. In addition, this ECD shows negligible decay in transmittance change after continuous 5,000 cycles at room temperature. In order to understand the mechanism behinds its fast-switching feature, an electrochemical quartz crystal microbalance (EQCM) is coupled with cyclic voltammetry (CV) to explore the ionic transport processes occur in both thin films.

Fig 1. Dynamic transmittance curves for the PProDOT-Et<sub>2</sub>/PG1 ECD switched with an interval of 5 s.

Fig 2. Cycling stability data for the PProDOT-Et<sub>2</sub>/PG1 ECD with a switching interval of 2 s.

Solar cell conversion efficiency can be improved by optimizing many key factors, including surface reflectivity. In this work we used an anisotropic wet chemical etching method combined with metal additive assisted chemical etching to form various silicon structures on the wafer's surface to evaluate their reflectivity. We investigated the effect of various additive metal compounds ( $\text{FeCl}_3$ ,  $\text{CoCl}_2$ ,  $\text{NiCl}_2$ ,  $\text{SnCl}_4$ ,  $\text{AgNO}_3$ ,  $\text{CuSO}_4$ ), together with variations in their concentrations, the reaction times allowed and the reaction temperature. This work, by relating solar energy conversion efficiency to the cell's surface morphology, shows the crucial importance of surface design optimization to the resulting final cell's performance. Metal-assisted wet chemical etching is an efficient method to fabricate, we investigated several kinds of metal ion compound and we found there are two compound react interesting. Hence, we decide to go deep into this two compound  $\text{CuSO}_4$  and  $\text{FeCl}_4$ . In our research, we consider the reaction times, reaction temperature and concentration of metal ion compound in order to observe the morphology of silicon wafer, electrochemical reaction and reflectivity, confirm it with SEM, potential state and UV-vis, respectively.

Here the approach of synthesis involves anchoring of Pt nanoparticles on the  $\text{Ti}_{1-x}\text{Mo}_x\text{O}_2$  nanosupports. While the structural defects of  $\text{Ti}_{1-x}\text{Mo}_x\text{O}_2$  are made by doping Mo into anatase  $\text{TiO}_2$  structure and hydrogen treatment at high temperature ( $300^\circ\text{C}$ ). The structural of this material were studied by the experimental Raman, electronic conductivity measurements.

Rotating disk electrode (RDE) measurements showed that 20wt% Pt/ $\text{Ti}_{0.9}\text{Mo}_{0.1}\text{O}_2$  catalyst had 1.5 times and 9.1 times higher Pt mass activity for ORR than those of 10 wt% Pt/ $\text{Ti}_{0.9}\text{Mo}_{0.1}\text{O}_2$  and commercial Pt/C catalysts, respectively. The observed high activity of metal oxide supported Pt catalyst could be attributed to the role of the advanced oxide support with electron donation from support to Pt catalyst surface, oxygen vacancies on nanosupport surface and high conductivity. Pt nanocatalysts on the advanced robust non carbon  $\text{Ti}_{0.9}\text{Mo}_{0.1}\text{O}_2$  nanosupports also exhibits improved stability against Pt sintering under a potential cycling regime (3000 cycles from 0.4 V to 1.0 V vs. RHE) due to strong metal support interaction (SMSI) between Pt catalyst and support materials. This approach can be extended to the different catalysis reactions such as CO oxidation, hydrogenation, etc.

# Electrochemical synthesis of hydrogen peroxide coupled with UV-C for the oxidation of endocrine disruptor compounds

R.J.M. Bisselink, L.Feenstra  
TNO dept. of Water Treatment  
Utrechtseweg 48, 3704 HE Zeist, the Netherlands  
Roel.Bisselink@tno.nl

Hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) can be applied in various markets (e.g. disinfection, waste water treatment and the pulp & paper industry). The current application of hydrogen peroxide however still requires shipment, handling and storage and therefore sufficient safety precautions. On-site or in-situ production of hydrogen peroxide therefore has clear advantages. Another attractive benefit is that only oxygen (or air) and electricity is needed for the electrochemical production of hydrogen peroxide. Within our laboratory we achieved concentrations up 10% hydrogen peroxide using a plate-and-frame electrolyser. This setup showed with previous research that efficient indirect oxidation of various reactive dyes could be achieved [1]. The same setup was used in this research in which we investigated the indirect oxidation of endocrine disruptor compounds (EDCs) originating from hospital waste waters. Eight compounds being caffeine, diclofenac, ifosfamide, ( $\pm$ )-metoprolol, naproxene, pentoxifylline, ( $\pm$ )-sotalol and trimethoprim were selected due to their presence in the hospital waste water. Hydrogen peroxide was produced under constant current and two types of UV-C lamps were employed to assess its effect on the oxidation. Characterisation of the system indicated that hydrogen peroxide was produced with near to 100% current efficiency.

# Indium recovery from secondary sources by electrowinning

R.J.M. Bisselink, M.A.C. Panjer  
TNO dept. of Water Treatment  
Utrechtseweg 48, 3704 HE Zeist, the Netherlands  
Roel.Bisselink@tno.nl

The increasing amount of electronics, such as consumer products and green technologies (e.g. solar PV cells) increases demand of metals such as indium. The European Commission has placed indium amongst a list of materials classified as critical [1]. The increasing demand of these critical metals together with the dependency on import drives research to investigate the recovery of valuable metals from secondary sources, so called urban mining. Flat panel displays (FPD) and CIGS type PV cells were selected as source material for the recovery of indium. A hydrometallurgical process is under development within the RECLAIM project of which electrowinning is the final step. Solvent extraction is used prior to electrowinning to purify indium and uses hydrochloric acid as stripping acid, as it enables selective stripping of indium [2]. In this research, we investigated the electrodeposition of indium using cyclic voltammetry and chronoamperometry. Cyclic voltammetry at graphite shows that the potential for indium electrodeposition is separated from the hydrogen evolution potential with approx. -0.4 V. Chronoamperometry will be used to investigate the influence of electrode potential, indium concentration and impurities on the current efficiency and product purity amongst others.

**Figure 1** Cyclic voltammogram of 10 g/l indium(III) in 1 M HCl at graphite.

# Electrochemical oxidation of Disperse Yellow 3 dye using BDD electrodes

Cláudio Márcio de Castro, Paulo Olivi

*Departamento de Química, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto*

The increase of industrial activities and the production of dyes resulted in environmental problems due to the generated effluents<sup>1</sup>. Among the various types of azo dyes, Disperse Yellow 3 (DY3) presents carcinogenic potential<sup>2</sup> and needs to be removed from wastewaters.

In this work the electrochemical oxidation of DY3 on boron-doped diamond anode (BDD) was investigated in different conditions as an alternative to degrade it and to produce less toxic effluents.

Electrolyzes performed in sulfuric acid medium indicate that it was possible to decrease the solution absorbance and to mineralize DY3 dye using BDD anodes. Cyclic voltammetry results showed that the dye does not present oxidation or reduction peaks, which suggest that the DY3 degradation does not occur directly and may occur indirectly due to the formation of oxidant agents.

The increment of sulfuric acid concentration or the increasing of the concentration of sulfate ions, results in a higher efficiency of the dye degradation. The result suggests that the DY3 degradation occurs mainly due to the sulfate radical formation from the interaction of hydroxyl radicals generated on the surface of BDD and sulfate ions. Electrolyzes carried out in nitric acid/sodium nitrate solutions confirms that the presence of sulfate is an important factor in order to obtain high degradation degree.

Percentage removal of TOC in different electrolytes in solution of pH 0,5 and ionic strength of 1,95 mol L<sup>-1</sup> after 2 hours of electrolysis.

Electrochemical technologies are an efficient alternative for the removal of pesticides from wastewater and soil [1]. Their main operational cost and environmental impact is associated with the use of electricity. A way to minimise this impact is to use a renewable source of energy, which also allows the use of this technology in remote applications, where no grid electricity is available [2]. This work aims at coupling wind turbine and photovoltaic panels to Conductive-Diamond Electrochemical-Oxidation (CDEO) and to Electrokinetic Soil Flushing (EKSF), comparing the results obtained in the green remediation with those obtained when the systems are fed with a power supply. Pesticide 2,4 dichlorophenoxyacetic acid was used as model pollutant for all studies.

For EKSF remediation tests a horizontal methacrylate column (20 cm) with different compartments was used in order to compare the differences obtained with the different energy supplies. Reference experiments were carried out powering the systems potentiostatically using an electric field of  $1.0 \text{ V cm}^{-1}$ . The setup included two electrolyte compartments and reservoirs, using graphite as anode and cathode ( $10 \times 10 \text{ cm}^2$  each). Kaolinite was selected as a model low-permeability soil. The duration of the experiments was two weeks. Significant differences were obtained in the main parameters after this long period. Relevant amounts of the herbicide contained in the soil were removed in the three experimental setups. Main fluxes (electroosmosis and evaporation), changes in the most relevant parameters (pesticide concentration, total organic carbon, moisture conductivity and pH) during treatment and a complete post-mortem analysis are compared in order to give a comprehensive description of the most relevant processes occurring in the soil and to compare the performance of the remediation technology as a function of the electrical powering device used.

The CDEO of the wastewater polluted with pesticide were also studied using the PV array and the wind turbine and results were compared to those obtained powering the system galvanostatically with a power supply (reference experiment was carried out applying 3.0 A of the external current). In this case the experiments were shorter (two-days length). The electrolyses were applied to  $4 \text{ dm}^3$  of a solution containing  $100 \text{ mg dm}^{-3}$  2,4-D at natural pH (3.5) and  $3.0 \text{ g L}^{-1}$  NaCl as a supporting electrolyte. The mineralisation of wastewater was completely accomplished regardless of the way of powering the electrolytic cell, although differences in performance are clearly observed in the total organic carbon (TOC) and 2,4-D decays. These changes are explained in terms of the changing profile of the current intensity, which influences the concentrations of the oxidants produced and thereby the mediated electrolytic process.

Juanma.paz@me.com

Soil contamination is a well-recognized environmental problem. Electrokinetic remediation (EKR) is, probably, the only feasible alternative among the different *in-situ* techniques for the remediation of low-permeability soils. EKR consists of the electrochemically-induced mobilization of contaminants by establishing an electric potential difference between two electrodes inserted in the soil. During the EKR process, the transport of ionic contaminants (as e.g. heavy metals) is mainly due to electromigration, while non-ionic contaminants (as e.g. organic compounds) migrate mainly by electroosmosis.

EKR requires some kind of enhancement in order to make the technique selective (in the target contaminant) and efficient (in terms of remediation and energy consumption). For example, in the case of a Pb-contaminated calcareous soil or soils with high content of carbonates, it is necessary to prompt the dissolution of the Pb-containing minerals (normally carbonates) using acid, or to extract the Pb from those minerals into aqueous complexes using chelating agents.

**Figure:** a) Experimental results for EKR remediation in a 20 cm length horizontal column 2 mA cm<sup>-2</sup> using acid enhancement. b) Simulation results for Pb transport. c) Scheme of the experimental setup.

In this work, we present a theoretical and numerical model to describe the coupled electrochemically-induced reactive-transport phenomena taking place in EKR processes in Pb-contaminated calcareous soils. We present here experimental and simulation results for EKR treatments in horizontal column at different lab scales. Numerically and experimentally obtained removal and energy efficiencies are presented and compared, for different enhanced treatments; using acids (acetic acid, nitric acid), extracting agents (acetate ion, citrate ion, EDTA) and ion exchange membranes and at different scales.

\*E-mail: mmorimit@mail.doshisha.ac.jp

An MH/air secondary battery is one of the promising candidates for next generation energy storage devices, which has some distinctive features; for example, the discharge at the positive electrode uses oxygen in air, so that theoretically, there is no limitation on the active mass of the positive electrode and on the discharge capacity, leading a high theoretical energy density. We have been developing this battery to achieve such a high energy density, for which low polarization and high durability is important for the positive electrode. In our previous studies [1], nickel has been used as the conductive and catalyst-supporting material of the positive electrode, because of its high stability in strong alkaline solutions, while it is needed to improve the dispersibility of oxide catalysts on nickel powders to reduce the polarization of oxygen reactions during charge and discharge. In this study, we aimed to develop a new method to prepare oxide loaded nickel powders as the positive electrode's material, in which  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$  was used as the catalyst and was tried to uniformly disperse on nickel powders by modified co-precipitation and calcination method.

$\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$  was produced through co-precipitation and calcination process, which was calcination at 600 °C of the precipitates obtained from the metal salt solution containing Bi(III) and Ir(IV) by adding excess NaOH solutions. Nickel powders were added to the precursor solution before or after co-precipitation. The obtained oxide loaded nickel was characterized by XRD, SEM, and EDX and then used to prepare the positive electrode by mixing with PTFE, followed by pressing and heating at 370 °C. The polarization behaviors of the positive electrode were measured with a three-electrode cell, in which one side of the positive electrode faced 6 mol/L KOH solutions, and the other side to air.

XRD results of the product obtained by the addition of nickel powders after co-precipitation showed some diffraction peaks of  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$ , Ni, and NiO, for which NiO seems to be formed during heating of the precipitates at 600 °C. SEM images of the product showed  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$  particles on nickel powders, and the presence of the oxide was also supported by element distribution from EDX. Figure 1 shows the polarization curves of the positive electrode (a) prepared by using the  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$  loaded Ni powders. The polarization is higher than that obtained with another positive electrode (b) consisting of nickel,  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$ , and PTFE, in which nickel powders were mixed with the oxide particles separately prepared by co-precipitation and calcination process at the same conditions. The results suggest that a further modification of the process to form  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$  on nickel powders is needed to suppress NiO and reduce the oxide size in order to enhance the dispersibility of the oxide catalyst.

Oxygen reduction reaction (ORR) is known as the cathodic reaction in fuel cell or metal/air battery and needs a high overpotential over 300 mV, which is still an issue in such applications. While the typical catalyst in practical uses is only platinum nanoparticles as in PEFC, it has been reported that  $\text{SnO}_2$  coexisting platinum on carbon materials has an effect to decrease the overpotential [1], although  $\text{SnO}_2$  itself has lower activity for ORR than platinum. A similar situation has been found in  $\text{IrO}_2$ - $\text{Ta}_2\text{O}_5$  mixed oxide catalyst for oxygen evolution, where  $\text{IrO}_2$  is highly active and  $\text{Ta}_2\text{O}_5$  is inactive, but the mixed oxide can possess a higher catalytic activity for oxygen evolution than  $\text{IrO}_2$  [2]. Such  $\text{Ta}_2\text{O}_5$  effects are in acidic solutions and for oxygen evolution, and there has been no investigation for oxygen reduction and in alkaline media. From these backgrounds, this work tried to produce a hybrid oxide comprising  $\text{Ta}_2\text{O}_5$  existing on  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$  particles which are now being used as the bi-functional oxygen catalyst for metal hydride/air secondary battery by our group. This paper reports a possibility of hybridization of such pyrochlore type oxide with  $\text{Ta}_2\text{O}_5$  and the results on polarization for ORR in alkaline solutions.

$\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$  powders were prepared by co-precipitation and calcination of the precipitates obtained by adding excess NaOH solutions into the metal salt solution containing Bi(III) and Ir(IV). The obtained powders were coated with a Ta precursor solution, which was  $\text{TaCl}_5$  dissolved in ethanol, and then heated to obtain  $\text{Ta}_2\text{O}_5$  coated  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$ . Some conditions on the coating process and the heating temperature were examined, and the products were analyzed by XRD, SEM, and EDX. The polarization for oxygen reduction on the obtained hybrid oxide was measured with rotating disk electrode (RDE) and 0.1 mol/L KOH solutions and was compared to that on  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$ .

The preliminary results on the condition of  $\text{Ta}_2\text{O}_5$  production by direct thermal decomposition of  $\text{TaCl}_5$  showed that  $\text{Ta}_2\text{O}_5$  was produced by heating at 650 °C for a few minutes, so that the similar condition was applied to the Ta precursor solution to make  $\text{Ta}_2\text{O}_5$  on  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$ . Figure 1 shows the SEM image of the obtained product, which are almost the same as pure  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$  in size and form. However, EDX analysis indicated that tantalum existed on the particles uniformly and the Ta content was 13.2 at.% in maximum in total of Bi, Ir, and Ta. The surface morphology of  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$  particles was unchanged by Ta treatment, and it seems that  $\text{Ta}_2\text{O}_5$  growth is suppressed and nano  $\text{Ta}_2\text{O}_5$  is presented on  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$  surface, because no diffraction peak of  $\text{Ta}_2\text{O}_5$  was observed for the hybrid oxide. The obtained hybrid oxide and pure  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$  were separately loaded on a titanium disk with support by ionomers. For each case, the oxygen reduction current on RDE was recorded and showed a diffusion-limited current, although the onset potential of oxygen reduction was much lower than that measured with the air electrode using  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$  as the catalyst in another experiment by our group. Therefore, the detailed comparison of the hybrid oxide to pure  $\text{Bi}_2\text{Ir}_2\text{O}_{7-z}$  for oxygen reduction activity is still under progress, and such results will be also shown in this paper.

In the recent years, there is an increasing concern of agencies and scientific community about the use of pesticides because of their high risks to human health and the environment. In this context, the 2,4-dichlorophenoxyacetic acid (2,4-D) is a chlorinated phenoxy herbicide, widely used to control many types of broadleaf weeds. This systemic herbicide is considered moderately toxic by World Health Organization and it is known to affect the nervous system of humans and animals. Since this compound exhibit high water-solubility, lifetime and mobility, its continuous use may cause soil percolation and groundwater contamination.

Electrokinetic remediation (ER) of soil has become a leading technology in the treatment of low permeability contaminated soils due to the wide range of contaminants that can be eliminated (salts, metals and organic compounds) and to its operational flexibility. ER is based on the different processes that occur into the soil when a low DC electric potential is applied through a group of electrodes sited into the same soil: electromigration (movement of ions), electrophoresis (movement of charge particles) and electro-osmosis (movement of groundwater contained in the soil or water added to enhanced the operation conditions) (Lopez-Vizcaino et al., 2011; Lopez-Vizcaino et al., 2014).

In this context, the goal of this research has been to develop flushing electrokinetic technologies for the remediation of soil polluted with 2,4-D. To do this, experiments around 40 days of duration have been carried out in bench-scale set-ups (175 dm<sup>3</sup>), completely automatized. Electrical current, temperature, pH, humidity and pollutant concentration in electrolyte wells were daily monitored, and at the end of the experiments an in-depth post-mortem analysis of the complete soil sections was carried out.

Results show that during the electro-remediation process many processes controlled by electrochemical and non-electrochemical mechanisms take place simultaneously. Even in the case of low-permeability soil, gravity and evaporation fluxes are comparable to electrokinetic fluxes. Likewise, it was observed that 2,4-D is mobilized to the anode wells mainly by electromigration, and that it is also moved towards the cathode by electroosmotic drag. Results are discussed at the light of the present knowledge of the transport process and sound conclusions about the scale up of the process are drawn.

## Symposium 10

This study aimed to verify the efficiency of the electrochemical oxidation process for removal Disperse Red BG (DRBG) dye in aqueous solutions using different electrocatalytic materials: BDD, Ti/PbO<sub>2</sub>, Ti/Pt, and Ti/Ru<sub>0.3</sub>Ti<sub>0.7</sub>O<sub>2</sub> anodes. The results were obtained by applying different current densities (20 and 50 mAcm<sup>-2</sup>) at 25°C using different supporting electrolytes (Na<sub>2</sub>SO<sub>4</sub> 1.0 g L<sup>-1</sup> and NaCl 1.0 and 3.0 g L<sup>-1</sup>) under values of pH 3 and 7. The conditions were selected in order to mimic the real textile effluent discharge. The anodic oxidation of DRBG dye was monitored by COD, HPLC and spectrophotometry.

The results obtained showed that the solution remain colored after 180 min applying 20 mAcm<sup>-2</sup> all electrocatalytic materials, using Na<sub>2</sub>SO<sub>4</sub> as electrolyte, being more efficient for BDD follow by Ti/PbO<sub>2</sub> and Ti/Pt; while Ti/Ru<sub>0.3</sub>Ti<sub>0.7</sub>O<sub>2</sub> showed a poorly decolorization and DOC removal. At 20 mAcm<sup>-2</sup> only BDD electrode produces a total mineralization of the solution after 180 min of electrolysis.

Conversely, at NaCl medium, more efficient color removal was achieved using all electrodes. Decolorization and mineralization are depending of the applied density current and supporting electrolyte concentration. Ti/Ru<sub>0.3</sub>Ti<sub>0.7</sub>O<sub>2</sub>, BDD and Ti/PbO<sub>2</sub> reached >90% of COD and color removal in NaCl medium. By HPLC analysis, the behavior of DRBG during anodic oxidation using each anode was studied too. The corresponding kinetic analysis confirms the results mentioned before. Carboxylic acids formed during the mineralization of DRBG using each electrode were detected and quantified. The profiles of each acid depend of the anodic material, of the applied density current and supporting electrolyte.

Recently, renewable energy has received a lot of attention because of its comparative safety and cleanness. However, the areas where renewable energy can be supplied substantially are often far from energy demand areas. It is essential to develop the technology of transportation for renewable energy. One of the attractive solutions for this problem is using methylcyclohexane (MCH) - Toluene (TL) organic hydride as fuel. The MCH - TL organic hydride system is a valuable system for hydrogen storage and transportation using hydrogenation and dehydrogenation chemical reactions. In the energy supply areas, TL and  $H_2$  produced by renewable energy react to form MCH. In the energy demand areas, MCH reacts to form TL and  $H_2$ , and TL is transported back to the energy supply areas. In this way, MCH - TL organic hydride is reusable compound. However, the fuel cell using MCH directly as fuel has not been studied widely. In this study, we developed two types of organic hydride fuel cells. One is the direct type fuel cell, where MCH is directly supplied to anode. The other is the internal reforming type fuel cell, in which internal reforming catalyst which reforms MCH to  $H_2$  and TL is placed in front of the electrode.

We used the proton conducting electrolyte based on  $CsH_2PO_4/SiP_2O_7$  composite<sup>[1]</sup>, and Pt/C (Chemix,  $1.0 \text{ mg cm}^{-2}$ ) as electrodes. A gaseous mixture of MCH (4%),  $H_2O$  (30%) and  $N_2$  (humidified MCH gas) was supplied to the anode electrode, and a gaseous mixture of  $H_2O$  (30%),  $O_2$  and  $N_2$  (humidified Air gas) was supplied to the cathode electrode. These measurements were conducted at  $260^\circ\text{C}$  under these gases.

Fig. 1 shows the cell voltage and power density as a function of current density of MCH fuel cell operating at  $260^\circ\text{C}$ . In the direct type cell, the open circuit voltage is 0.71 V, and the maximum current density and power density are  $10.9 \text{ mA cm}^{-2}$  and  $2.4 \text{ mW cm}^{-2}$  at  $5.8 \text{ mA cm}^{-2}$  respectively. This result represents electric power generation using MCH directly as fuel. On the other hand, in the internal reforming type, the open circuit voltage is 0.74 V. Compared with the direct type cell, higher power density,  $3.4 \text{ mW cm}^{-2}$  at  $9.2 \text{ mA cm}^{-2}$  is observed. These results imply MCH is dehydrogenated to form TL and  $H_2$  through internal reforming catalyst, and  $H_2$  is supplied to anode. However, the observed power density is less than that using humidified  $H_2$  gas as fuels. Residual MCH or TL might impede the electrochemical reaction in the anode.

The light is being refocused on the value of the electrolysis market due to the renewable energy (especially in the increasing trend of the wind power and solar cell generation), the necessity of the energy storage system, and the applicability of electrolysis in the hydrogen station, and our research came to the conclusion that there is a solution for such a direction.

In order for the electrolysis to be actively applied in the industry, it not only has to have an advantage with regard to the efficiency but also in term of the cost. With such significance, the alkaline water electrolyzer which does not use expensive noble metal catalyst will be the most ideal electrolyzer.

In our lab, we used porous asymmetric high surface area nickel electrodes and manufactured stacks using such highly efficient electrodes.

In regard to the structural characteristic of electrodes, the obtained current density of the unit cell is close to  $600\text{mA}/\text{cm}^2$  at the voltage of  $1.8\text{V}$ , while also acquiring enough competence for commercialization in manufacturing cost and processing aspects.

Additionally in our lab, we have developed the miniaturized alkaline water electrolysis system through application the stack technique that we have, and now reviewing the applicability to the hydrogen station and HESS (Hydrogen Energy Storage System).

Plating wastewater contains various kinds of toxic chemical substances (*e.g.* acid cyanide, alkaline cleaning agent, and degreasing solvents) and heavy metals (*e.g.* copper, nickel, and chromium). Most of the heavy metals in wastewater are extremely harmful when they are discharged directly to the environment. Hence, providing an efficient treatment for removing or collecting these heavy metals before discharging becomes important and necessary. Copper (Cu) is one of most common heavy metal ion in the wastewater of printed circuit board (PCB) process. One of the most effective ways for collecting Cu ions is electrochemical process. Cu ions were removed with high efficiency from a dilute industrial effluent in an electrochemical reactor with plate electrode. However, additional direct current based power supplies are unavoidable part to drive it. Recently, self-powered systems have been developed to integrate variable devices into a standalone system with multiple functions, including sensing, communication, computation, *etc.* [1]. The wireless, miniaturized and the large number of components in the system require a renewable, sustainable and clean power supply, and energy harvesting from the ambient environment will be a perfect solution for this problem. In this regard, the triboelectric nanogenerator (TENG) was recently invented to convert the mechanical energy into electricity, based on the coupling effect of contact electrification and electrostatic induction. Here in this work, integrated bundle structure of rolling free standing triboelectric nanogenerator (IRF-TENG) with outstanding output performance and ultrahigh longterm stability was proposed for harvesting hydropower and further applied in self-powered electrochemical system for collecting Cu ions. With the above design, the IRF-TENG delivers an open-circuit voltage ( $V_{OC}$ ) up to  $\sim 450$  V and a short-circuit current of 0.2 mA under a rotation speed of 1000 rpm. Ultra robust characteristic can be fully realized by introducing the frictionless free standing TENG structure with rolling bearing for refilling its superficial charge. Moreover, several unit of rolling free standing TENG [2] can be integrated by means of incorporating with common mechanical gears to bring about the integrated bundle structure of rolling free standing TENG. By integrating with a power management circuit, stable DC output (5V, 4 mA) performance can be achieved by hydropower driven IRF-TENG to practically realize the concept of self-powered electrochemical system for collecting Cu ions. This work provides a significant progress of TENG and exhibits huge potential of the IRF-TENG as a high efficiency energy harvester for practical applications.

[ebustos@cideteq.mx](mailto:ebustos@cideteq.mx)

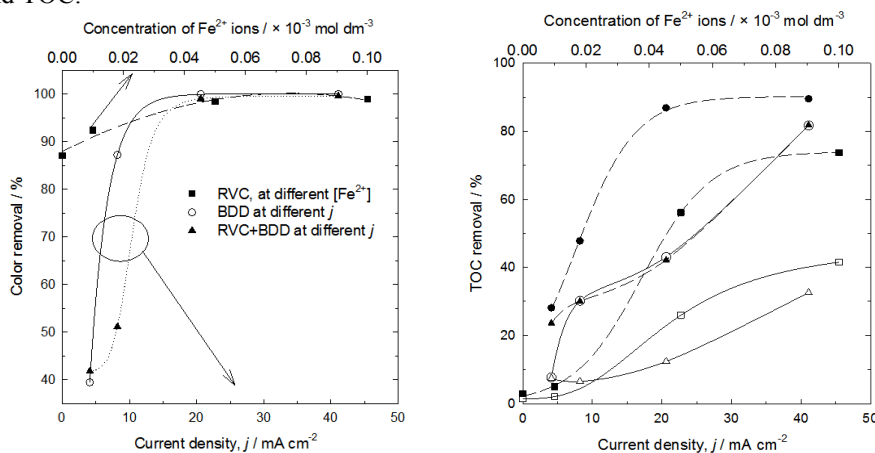

The purpose of geophysical electrical surveys is to determine the subsurface resistivity distribution by making measurements on the ground surface. From these measurements, the true resistivity of the subsurface can be estimated. The ground resistivity is related to various geological parameters, such as the mineral and fluid content, porosity and degree of water saturation in the rock.

Electrical resistivity surveys have been used for many decades in hydrogeological, mining and geotechnical investigations. More recently, they have been used for environmental surveys. To obtain a more accurate subsurface model than is possible with a simple 1-D model, a more complex model must be used. In a 2-D model, the resistivity values are allowed to vary in one horizontal direction (usually referred to as the  $x$  direction) but are assumed to be constant in the other horizontal (the  $y$ ) direction. A more realistic model would be a fully 3-D model where the resistivity values are allowed to change in all three directions. In this research, a simulation of the cone penetration test and 2D imaging resistivity are used as tools to simulate the distribution of hydrocarbons in soil.

# Electrochemical degradation of RB-5 dye by anodic oxidation, electro-Fenton and by combining anodic oxidation-electro-Fenton in a filter-press flow cell

I. Ishita, V.M. Vasconcelos, C. Ponce-de-León, M.R.V. Lanza, J.L. Nava  
Faculty of Engineering and the Environment, University of Southampton  
University Road, Southampton, SO17 1BJ

The removal of Reactive Black 5 (RB-5) was carried out by three methods; 1) anodic oxidation (AO) on Boron-Doped Diamond (BDD), 2) by electro-Fenton (EF) process where hydrogen peroxide was produced by  $O_2$  reduction on reticulated vitreous carbon (RVC) electrodes and 3) by the combination of AO-EF. The BDD and RVC electrodes were fitted in a filter-press flow cell in recycle batch mode of operation. The experimental set up for the AO and EF processes consisted on two electrolyte compartments separated by a Nafion membrane with the dye contained in the anolyte and the catholyte, respectively. The combined AO-EF process used only one electrolyte compartment. The color and total organic carbon (TOC) removal were more efficient when the AO and EF processes were used separately than the combined process, AO-EF. The influence of current density and initial concentration of ferrous ions were examined. The lowest energy efficiency ( $208 \text{ kWh kg}^{-1}$ ) with the EF process was found when  $-0.4 \text{ V vs Ag/AgCl}$  was applied to a RVC electrode and the concentration of  $Fe^{2+}$  was  $1.0 \times 10^{-4} \text{ mol dm}^{-3}$  achieving total color and 74% TOC removal in less than 90 min electrolysis. All the processes oxidize RB-5 dye completely and promote high percentages of TOC removal following a pseudo first order kinetic oxidation. The BDD electrode was the most effective material to remove RB-5 dye within 7.5 min and presented the highest apparent rate constant ( $0.835 \text{ min}^{-1}$ ) with 82% TOC removal within 30 min at an energy consumption of  $291 \text{ kWh kg}^{-1}$  and  $41.1 \text{ mA cm}^{-2}$  current density. In addition the results of using a mesh BDD electrode will be presented and compared with the electro-Fenton process in terms of energy consumption and TOC.

Color removal after 90 minutes of electrolysis (left) and TOC removal (right) at 30 minutes and 90 minutes of electrolysis: □) RVC at  $-0.4 \text{ V vs Ag/AgCl}$  varying  $Fe^{2+}$  ions, ○) BDD and △) RVC + BDD varying the current density. TOC removal at 90 minutes: ■) RVC at  $-0.4 \text{ V vs Ag/AgCl}$  varying  $Fe^{2+}$  ions, ●) BDD and ▲) RVC + BDD varying the current density. Supporting electrolyte  $0.5 \text{ mol dm}^{-3}$  of  $Na_2SO_4$  at  $23^\circ \text{C}$ , flow rate  $100 \text{ dm}^3 \text{ h}^{-1}$ . Initial concentration of RB-5 dye  $20 \text{ mg dm}^{-3}$ .

## Combined soil washing and CDEO for the removal of oxyfluorfen from soils

Santos, E.V.<sup>1</sup>, C. Sáez<sup>2</sup>, Martínez-Huítile, C. A.<sup>1</sup>, Cañizares, P.<sup>2</sup>, M.A. Rodrigo<sup>2</sup>

<sup>1</sup>Federal University of Rio Grande do Norte, Natal, Brazil

<sup>2</sup>Universidad de Castilla-La Mancha, Ciudad Real, Spain

e-mail: elisama\_quimica@yahoo.com.br

Oxyfluorfen is a diphenyl-ether herbicide used for broad spectrum pre- and post-emergent control of annual broadleaf and grassy weeds in a variety of tree fruit, nut, vine, and field crops. The largest agricultural markets in terms of total pounds active ingredient are wine grapes and almonds. There are also non-agricultural ornamental and forestry uses. For this reason, it is very important the rapid actuation against accidental discharges of hazardous species with efficient technologies that remediate the soil rapidly and avoids diffuse pollution. The objective of this study was to investigate under laboratory conditions the behavior of oxyfluorfen in soils consisting of the soil washing with a sodium dodecyl sulphate solution followed by the electrolysis with BDD anodes of the resulting wastewater. Effect of the ratio surfactant /soil is going to be assessed trying to determine its influence in the soil washing efficiency and in the characteristics of the washing waste. Samples of polluted soil (kaolinite) were polluted with a solution prepared by dissolving oxyfluorfen in acetonitrile. The surfactant-aided soil-remediation was carried out in a stirred batch tank. The tank volume was 800 cm<sup>3</sup>. Low-permeability soil (1000 g) was used and polluted with 100 mg oxyfluorfen, adding 800 cm<sup>3</sup> of solubilizing agent (containing deionized water with different amounts of 100, 500, 2500 and 5000 mg dm<sup>-3</sup> of surfactant and 500 mg dm<sup>-3</sup> of NaHCO<sub>3</sub>). Degradation was monitored by total organic carbon (TOC), chemical oxygen demand (COD) reduction and concentration of SO<sub>4</sub><sup>2-</sup>, Cl<sup>-</sup>, ClO<sup>-</sup>, ClO<sub>3</sub><sup>-</sup> and ClO<sub>4</sub><sup>-</sup>, as function of electric charge passed (Q), during galvanostatic electrolysis of simulated effluent solution (700 dm<sup>-3</sup>) using BDD anodes by applying 30 mA cm<sup>-2</sup> at 25 °C. The particle size decreases during the electrochemical process because the electrolysis helps to break the emulsion, especially when dispersed particles are present in the solution Fig. 1. Surfactant aided soil washing with SDS solutions is an efficient technology from the removal of oxyfluorfen from spiked soils. Characteristics of the effluents obtained in the SASW process depends largely on the SDS/soil dosage. In spite of having the same chemical compounds, effluents are and behave in a completely different way, in particular because of the very different type of microdrops. Opposite to other AOP production, production of intermediates is almost negligible in this process. Only 4-(trifluoromethyl)-phenol and ortho-nitrophenol, coming from the oxidation of oxyfluorfen, were detected by HPLC. No intermediates coming from SDS were detected in spite of the high concentrations of SDS in various of the effluents. This indicates that intermediates formed during the process are very rapidly oxidized and that most important processes occurs on the micelles surfaces.

# Extraction Agents for Removing Petroleum from Soil and Application of Electrolysis to Treat Washing Fluid

E.V Santos<sup>1</sup>, C. Sáez<sup>2</sup>, P. Cañizares<sup>2</sup>, M.A. Rodrigo<sup>2</sup>, C.A. Martínez-Huitle<sup>1</sup>

<sup>1</sup>*Federal University of Rio Grande do Norte, Natal, Brazil*

<sup>2</sup>*Universidad de Castilla-La Mancha, Ciudad Real, Spain*

*e-mail: [elisama\\_quimica@yahoo.com.br](mailto:elisama_quimica@yahoo.com.br)*

Petroleum in soil has been recognized as a serious health and environmental issue due to their carcinogenic, mutagenic and teratogenic properties. One of the commonly employed soil remediation techniques to clean up such contamination is soil washing or solvent extraction. It consists on the extraction of pollutants contained in the soil with a solution that helps to obtain an efficient transfer of the pollution from the soil to a liquid phase. In fact, it can be considered as a soil-liquid extraction operation unit, in which the pollutant is transferred from the solid soil to the liquid washing fluid. In the case of organics, the use of surfactant solutions is the most extended application. In order to treat this waste, efficient technologies have to be used as electrolysis with diamond electrodes because of its great robustness and efficiency. It may attain the total removal of pollution by mineralization. This work aims to evaluate the effectiveness of a treatment of a soil spiked with petroleum, consisting of the soil washing with a sodium dodecyl sulphate solution followed by the electrolysis with BDD anodes of the resulting wastewater. Effect of the ratio surfactant/soil is going to be assessed trying to determine its influence in the soil washing efficiency and in the characteristics of the washing waste. Samples of soil (kaolinite) were polluted with a solution prepared by dissolving petroleum in hexane. The surfactant-aided soil-remediation was carried out in a stirred batch tank. The tank volume was 800 cm<sup>3</sup>. Low-permeability soil (1000 g) was used and polluted with 5000 mg petroleum, adding 800 cm<sup>3</sup> of solubilizing agent (containing deionized water with different amounts of 100 at 5000 mg dm<sup>-3</sup> of surfactant and 500 mg dm<sup>-3</sup> of NaHCO<sub>3</sub>). Degradation was monitored by total organic carbon (TOC), chemical oxygen demand (COD) reduction and concentration of SO<sub>4</sub><sup>2-</sup>, Cl<sup>-</sup>, ClO<sup>-</sup>, ClO<sub>3</sub><sup>-</sup> and ClO<sub>4</sub><sup>-</sup>, zeta potential and mean size particle as function of electric charge passed (Q), during galvanostatic electrolysis of simulated effluent solution (700 dm<sup>-3</sup>) using BDD anodes by applying 30 mA cm<sup>-2</sup> at 25 °C. This process transfers the pollution from the soil to a soil washing solution, which becomes wastewater. Comparing the two effluents, it can be observed that the effluent of treatment 2 (with a higher concentration of surfactant in the washing fluid) has a much higher COD and TOC but mean size of particles is much smaller and superficial charge is much more negative. Conversely, in effluent of treatment 1 both petroleum and surfactant are contained in the same mass concentration. This means that very different results are expected when both effluents are treated by electrochemical technologies.

The electrochemical oxidation (EO) is presented as an alternative clean, efficient and economical for treating wastewater containing organic compounds [1]. However, it still needs some amendments concerning their mechanisms and kinetics followed. Comninellis and his research a group [2] have elucidated a theoretical model that permits us to predict the chemical oxygen demand (COD) and instantaneous current efficiency (ICE), during the EO of organic pollutants on synthetic boron-doped diamond electrodes (BDD) in a batch recirculation system under galvanostatic conditions. Several studies highlight the good correlation between theoretical predictions and empirical data, but it was noted that some data, from some experiments, were not in agreement with the theoretical model, since it achieved efficiencies above 100% [1,2,3]. Few studies [1,3] have reported phenomena that occur in electrocatalytic systems which were not deducted in the first models. Thus, we emphasize that the mineralization of organic compounds on BDD electrodes involves not only hydroxyl radicals but also the molecular oxygen present in air, in saturated aqueous solutions or strong oxidants generated from simultaneous reactions, as already showed by Comninellis [2]. Also, the identification of intermediates during EO of 2-naphthol were performed as well as theoretical chemistry calculations that confirms our assertions. With this information, this research attempts to show related phenomena anomalies from electrochemical oxidation of 2-naphthol using BDD anodes and varying the current density. The possibility of a correction to the Comninellis' model could be an important advance in the understanding of this process for its scale-up. Currently the performance of the electrocatalytic process is established by a complex interaction between different parameters that can be optimized, so it is necessary to the implementation of theoretical models to considered new phenomena.

# Electrochemical reduction of carbon dioxide to formic acid at tin cathode in divided and undivided cells: effect of operating parameters

Onofrio Scialdone, Simona Sabatino, Alessandro Galia

*Università degli Studi di Palermo*

*Viale delle Scienze, 90100 Palermo*

*onofrio.scialdone@unipa.it*

The electrochemical reduction of carbon dioxide is considered a relevant topic for both the synthesis of chemicals and the decrease of global warming. Indeed, the utilization of CO<sub>2</sub> as a feedstock for producing chemicals may contribute to alleviate global climate changes caused by the increasing CO<sub>2</sub> emissions and provide a relevant challenge in exploring new opportunities for catalytic and industrial development. Electrochemical processes could utilize excess energy from intermittent renewable sources to convert carbon dioxide in various products such as CO, formate and formic acid, methane and ethylene in water and oxalic acid, formic acid, CO as well as carboxylic acids (by reaction with suitable reagents such as aromatic ketones or benzylic halides) in aprotic solvents [1-3]. It has been shown that the selectivity of the process dramatically depends on the nature of the cathode. Four distinct classes of metal catalysts have been identified on the bases of the main products obtained by the cathodic reduction in water: (i) metals that mainly form formic acid (Pb, Hg, In, Sn, Cd, Ti); (ii) metals that mainly form carbon monoxide (Au, Ag, Zn, Pd, Ga); (iii) metals that mainly form H<sub>2</sub> (Pt, Ni, Fe, Ti); (iv) metals that form significant amounts of hydrocarbons such as methane and ethylene (Cu) [2]. In the last years, an increasing attention has been devoted to the conversion of carbon dioxide to formic acid in water. In particular, it has been shown that the utilization of cheap tin cathodes allow the production of formic acid with good Faradic Efficiencies (FE) [4-14], even higher under suitable operating conditions than that obtained at lead cathode [8].

Here, a study on the effect of some operating parameters on the electrochemical reduction of carbon dioxide to formic acid at tin cathode in divided and undivided cells will be presented.

# On the continuity of chlorine production during electrochemical water disinfection

M.E.H. Bergmann  
Anhalt University, Köthen  
Bernburger Str. 55, D-06366 Köthen/Anh., Germany  
h.bergmann@emw.hs-anhalt.de

Direct electrochemical water disinfection is known for many decades of years but not yet legal for drinking water treatment in Germany. The method is known under several brand names such as *Inline Electrolysis*, *Anodic Oxidation*, *Tube Electrolysis*, and others [1]. The simplicity of forming chlorine species from dissolved chloride inside a divided or mostly undivided electrochemical cell is contrasted by blocking effects at the cathode – due to calcareous deposits (problem of water hardness). On-site chlorine production from artificial electrolytes is a way-out but seldom used. As a consequence, electrolysis must be interrupted. During a more or less shorter time, cathodes have to be cleaned by mechanical or chemical means. Another solution is the periodic change of electrode polarity to dissolve deposits anodically. Sophisticated cell constructions separate removed deposit particles using a special trapping zone.

Unfortunately, there is no method to make prognosis on the right time for electrode cleaning. Several methods such as potential monitoring and switching routines were tested in natural and artificial waters using lab-scale and technical cells mostly at room temperature. Only quartz microbalance measurement showed sufficient results. Unfortunately, this technology is not practicable under technical conditions. Change of electrode polarity may be responsible for 2 main effects: In periods of changing the polarity chlorine production is often temporarily interrupted and/or disturbed over a few minutes (Fig.1).

Furthermore, if calcareous deposits cannot be completely removed, a long-term reduction of free active chlorine production can be observed – lowering disinfection efficiency. The first effect should not be a general problem because minimization of chlorine addition is part of legislation for drinking water (dictate of minimization). Surprisingly, water authorities demand continuous chlorine production in places of possible application. Currently, the use of 2 alternately working cells is the most promising method to solve the problem.

**Fig. 1** Total chlorine concentration under normal conditions (technical bipolar cell, no separator, tap water, 14-17 °C) and during periods of changing electrode polarity.

In addition, technical cell must be equipped with means of chlorine concentration measurement to guarantee sufficient chlorine concentration level.

Reverse electrodialysis is sustainable technology for generating energy from the mixing of concentrated salt solutions (e.g., sea water) and diluted salt solutions (e.g., river water) with different salinity. In RED a stack is alternating series of cation-exchange membranes (CEMs) and anion-exchange membranes (AEMs) between two electrodes that selectively transfer anions and cations. The main drawback to use ion-selective membranes is fouling to cause the difficulty in maintaining continuous operation and maintenance cost. In this study, the simulated foulants that might cause the membranes fouling existing in the sea and/or river water were proposed. This simulated foulants influenced membrane surface due to the electrostatic characteristics between the ion exchange membranes and the foulants. The influence of membrane fouling on the operating parameters in RED was investigated experimentally using various simulated foulants (i.e., natural organic matters and divalent ions), and open circuit voltage, stack resistance, and power density were measured and compared at different operation conditions.

Currently consumable carbon anodes are utilized in the aluminium production process in molten salts. One of the major drawbacks of this type of anodes is the high amount of CO<sub>2</sub> emissions. Introduction of natural gas through the anode can decrease CO<sub>2</sub> emissions significantly and reduce consumption of the anode. This concept has been tried before [1-2] and promising results were found in some studies. The use of inert porous anodes is interesting since the energy demand would be reduced due to natural gas participating in the anode reaction. However, due to unavailability of a sufficiently inert anode for aluminium electrolysis until now, carbon anodes remain more attractive. On the other hand, using CH<sub>4</sub>/H<sub>2</sub> can lead to the formation and evolution of additional hydrogen fluoride. In this study, laboratory experiments were performed and carbon anodes with different graphite grades and porosities were tried. Also, the effects of other experimental parameters such as current density and gas flow rate were studied. Off-gas analysis was also performed and off-gas composition is discussed. Our preliminary results show that the methane participates in the anodic reaction. This leads to decreased carbon consumption.

*Antonio.Lconsuegra@uclm.es*

Different strategies are being developed to mitigate the global warming and climate change, which are mainly focused on the separation, storage and utilization of CO<sub>2</sub>. In this sense, hydrogenation of CO<sub>2</sub> can be considered as one of the most important chemical conversion reaction not only for the effective decrease of the overall CO<sub>2</sub> emissions but also for the production of many possible renewable fuels (hydrocarbons or alcohols). In this regard, different Ni catalysts films were prepared on K-βAl<sub>2</sub>O<sub>3</sub> by combining the organometallic paste deposition and the addition of a α-Al<sub>2</sub>O<sub>3</sub> powder, and tested in the CO<sub>2</sub> hydrogenation reaction. The complete characterization and its electrocatalytic performance were investigated in this work.

Figure 1 shows the influence of the applied potential on the steady-state variation of the selectivity toward CO and CH<sub>4</sub> at different temperatures (T = 240, 270 and 300 °C) with different feed composition (H<sub>2</sub>/CO<sub>2</sub> = 2-20 %). CO and CH<sub>4</sub> were already produced by means of the reverse water gas-shift: CO<sub>2</sub> + H<sub>2</sub> → CO + H<sub>2</sub>O and CO<sub>2</sub> methanation: CO<sub>2</sub> + 4H<sub>2</sub> → CH<sub>4</sub> + 2H<sub>2</sub>O. At all temperatures, the decrease in the applied potential led to a strong increase in the CO selectivity (electrophilic behavior) and a decrease of the CH<sub>4</sub> selectivity (electrophobic behavior). For instance, with a H<sub>2</sub>/CO<sub>2</sub> ratio of 20, the selectivity of the Nickel catalyst toward CO production was enhanced up to more than 95 %, depending on the reaction temperature. In the present work, under unpromoted conditions, a value of 50 % was obtained. Moreover, CH<sub>4</sub> production rate was increased against CO production at higher H<sub>2</sub> concentrations. The decrease in temperature also enhanced the methanation selectivity. Depending on both the applied potential and the reactions conditions, one can control the Ni activity and the selectivity toward CO and CH<sub>4</sub> by means of the controlled migration of K<sup>+</sup> ions from a solid electrolyte. Hence, one could in-situ control the preference formation of syngas or CH<sub>4</sub> production rate via CO<sub>2</sub> hydrogenation, which may be of significant practical importance.

**Figure 1.** Effect of the applied potential ( $U_{WR}$ ) and the H<sub>2</sub> feed concentration on the selectivity of CH<sub>4</sub> and CO, at (a) 240 °C, (b) 270 °C and (c) 300 °C. Reactions conditions:  $F_T = 6 \text{ NL} \cdot \text{h}^{-1}$ .

# A Novel Processing Method and Simulation Based on Confined Etching Layer Technique

Lianhuan Han, Jie Zhang, Pei Huang, Dongping Zhan\*, Zhong-Qun Tian

Department of Chemistry, College of Chemistry and Chemical Engineering, and State Key Laboratory of Physical Chemistry of Solid Surfaces, Xiamen University, Xiamen 361005, China.

E-mail: dpzhan@xmu.edu.cn

Confined etchant layer technique (CELT) is a chemical etching technique induced by in-situ photo/electrochemistry and has been successfully applied to fabricate 3D microstructures for many kinds of materials, such as metals, metal alloys and semiconductors,[1] which is a replication technique with high-precision. Combined the relative motion between tool and substrate, a quasi-1D tool with large length-width ratio is designed and manufactured to perform large-scale machining with micro- or nano-precision. In this way, the mass transfer efficiency could be enhanced and the mass balance could be maintained easily. The etching reaction of substrate is supposed a simple reaction (K1) with a following reaction which could reach the absorption equilibrium (K2). The diffusion model coupled with deformed geometry model and laminar flow model in commercial finite element package Comsol Multiphysics is used to simulate the whole etching process. The profiles simulated fits well with experiment in different etching time and tool-substrate distances when K1 is  $3.2 \times 10^{-4} \text{ m s}^{-1}$  [2] and K2 is 0.01. In rotary motion model, an irregular GaAs surface is obtained after etching process. The simulation result has the similar profile also.

Fig. 1 The cross-sectional profile (solid line) of GaAs substrate etched in different time (a) and different tool-substrate distance (b); the corresponding cross-section simulated by deformed geometry model (symbols). The solution is 0.1 M NaBr and 1 M  $\text{H}_2\text{SO}_4$  with 50mM L-Cystine.

Fig. 2 (a) Optical image of an irregular surface obtained on a GaAs workpiece through the coupling effect of the CELT etching system and the mechanical motion; the rotating speed is 2.09 rad /s and the tool-substrate (GaAs) distance is 10  $\mu\text{m}$ ; (b) profilometric results of the irregular surface; (c) a preliminary 3D simulation image of the obtained irregular surface; (d) simulation result of the lateral profile of the irregular surface.

# Simultaneous Removal of COD and Ammonia Nitrogen using a Novel Electro-oxidation Reactor

Jiade Wang, Mingming Zhou, Guolong Huang, Yongping Gan

*College of Biological & Environmental Engineering, Zhejiang University of Technology, Hangzhou 310032, China, jdwang@zjut.edu.cn*

Electro-oxidation, one kind of advanced oxidation processes, has been gradually used to treat industrial wastewaters containing biorefractory compounds. A novel plug flow electrochemical reactor with porous reticulated electrodes was used to removal COD and ammonia nitrogen from pharmaceutical wastewater.

The results showed that COD and ammonia nitrogen were removed simultaneously. Under the optimal operating conditions with the initial pH of 8.3, the current density of 15 mA/cm<sup>2</sup> and the electrolysis time of 40min, concentrations of COD, ammonia nitrogen and color were decreased to 12.98 mg/L, 23.74 mg/L and 2 Hazen, respectively. Meanwhile, the amount of microbes in wastewater reduced from 7×10<sup>4</sup> CFU/ml to 0 CFU/ml.

In the actual engineering project with daily treatment capacity of 500 m<sup>3</sup>, the energy consumptions were 30.81 kW·h·kg<sup>-1</sup> COD and 28.39 kW·h·kg<sup>-1</sup> NH<sub>3</sub>-N. The average current efficiencies for COD and ammonia nitrogen reduction were 33.71% and 63.15%, respectively. The operating cost was \$ 0.8 per ton according to the local electricity price of \$ 0.14·kWh<sup>-1</sup> for industries. There were many advantages, such as strong adaptability, no adding chemicals, little or no secondary pollution, mild reaction conditions and simple equipment, etc. So, the electro-oxidation method had the strong prospect for the industrial wastewater treatment.

# Solid State Ammonia Synthesis – Present State and Perspective

Chung-Yul Yoo, Dae Sik Yun, Jong Hoon Joo, Ji Haeng Yu, Jong-Nam Kim, Hyung-Chul Yoon  
Korea Institute of Energy Research  
152 Gajeong-ro, Yuseong-gu, Daejeon 305-343, Republic of Korea  
cyoo@kier.re.kr

Ammonia has a potential as a carbon-free energy carrier since it contains 17.6wt% of hydrogen and can be easily stored and transported safely and efficiently [1]. The state-of-the-art industrial process for ammonia production is the Harbor-Bosch process. Although high temperature (450–500 °C) and pressure (150–300 bar) are used to dissociate triple-bonded nitrogen and to maximize the ammonia formation, the efficiency of the Haber–Bosch process is limited to 10–15%. Moreover, the process accompanies high greenhouse gases emission since hydrogen is produced from natural gas. In order to overcome the drawbacks of the Haber-Bosch process, the electrochemical ammonia synthesis has been developed as an alternative process [2, 3].

In this work, we have conducted systematic experiments on the electrochemical ammonia synthesis from nitrogen and steam using various solid state ion conductors. Perovskite- and fluorite-type oxides, solid acid phosphate, and Nafion have been employed to investigate the effects of temperature, applied current, and electrocatalyst on the ammonia formation rate [4-6]. The obtained ammonia formation rates and Faraday efficiencies are summarized in Table 1. Some of remaining challenges are outlined for further research.

Table 1 Summary of ammonia formation rate and Faraday efficiency.

Electrolyte (Mobile ion)	N <sub>2</sub> dissociation electrocatalyst	°C	NH <sub>3</sub> rate (mol·cm <sup>-2</sup> ·s <sup>-1</sup> )	Faraday efficiency (%)

# Removal of Persistent Organic Contaminants by Electrochemically Activated Sulfate

Ali Farhat<sup>a</sup>, Stephan Tait<sup>a</sup>, Jurg Keller<sup>a</sup>, Jelena Radjenovic<sup>a,b</sup>

<sup>a</sup> Advanced Water Management Centre, The University of Queensland, Queensland 4072, Australia

<sup>b</sup> Catalan Institute for Water Research (ICRA), Scientific and Technological Park of the University of Girona, 17003 Girona, Spain  
e-mail: a.farhat@awmc.uq.edu.au

The incomplete removal of persistent organic compounds such as pharmaceuticals and pesticides in conventional water and wastewater treatment plants have raised the interest for novel technologies capable of effectively degrading such organic contaminants. Electrochemical advanced oxidation processes (EAOPs) employing boron doped diamond (BDD) anodes have been previously reported to accomplish significant degradation of such trace organic contaminants. Previous studies have shown that BDD anodes are characterized with high overpotential for oxygen evolution where such anodes enhance the degradation rates of organics via direct oxidation and production of weakly adsorbed hydroxyl radicals (HO<sup>•</sup>). Besides HO<sup>•</sup> and other radical species, BDD anodes can also produce peroxy-species that may also contribute to bulk oxidation of contaminants. For example, previous research has reported BDD anodes are capable of oxidizing sulfate ions to peroxydisulfate (S<sub>2</sub>O<sub>8</sub><sup>2-</sup>), via sulfate radicals (SO<sub>4</sub><sup>•-</sup>) as intermediate products.

To further explore the role of sulfate in EAOPs, the present study quantified the rates of electrooxidation of several persistent organic contaminants (e.g., diatrizoate, carbamazepine, N,N-diethyl-meta-toluamide (DEET), iopromide, tribromophenol, triclosan and triclopyr) at BDD anode. Experiments were performed in sulfate anolyte at different operating conditions (concentrations/conductivities and current densities) and compared with inert nitrate and perchlorate anolytes. The observed electrooxidation rates of the persistent organic contaminants in sulfate anolyte were in the range of 12 – 66 h<sup>-1</sup>, significantly higher than the values obtained for nitrate anolyte (0.83 – 5.4 h<sup>-1</sup>).

Given that in the absence of trace metals or other activators (e.g., UV light), persulfate was shown to exhibit slow oxidation kinetics with these persistent organic contaminants (k < 0.1 h<sup>-1</sup>), higher electrooxidation rates in the presence of sulfate were assigned to the electrochemical activation of sulfate ions to sulfate-based oxidizing species such as sulfate radicals (SO<sub>4</sub><sup>•-</sup>) and/or non-radically activated persulfate. In an attempt to segregate the effects of HO<sup>•</sup> radicals and SO<sub>4</sub><sup>•-</sup> radicals, the study also examined the electrooxidation of nitrobenzene at a BDD anode, as a typical HO<sup>•</sup> radical probe compound, and provided further evidence for the presence of SO<sub>4</sub><sup>•-</sup> radicals.

Sulfate-based solutions have been widely used as supporting electrolytes for electrochemical degradation of contaminants using BDD anode. Electrooxidation pathways have been largely explained by the role of HO<sup>•</sup> radicals and other reactive oxygen species. Our results imply electrochemical activation of sulfate ions, even at sulfate concentrations as low as 150 mg L<sup>-1</sup>. Thus, this study has implications in applications of BDD anodes in wastewater treatment, as the presence of sulfate may significantly affect the electrooxidation pathways and kinetics of persistent organic contaminants.

# Intact Recovery of Carbon Nanotubes from their Conducting Polymer Composites via Selective Fenton-Oxidation

Li Guan<sup>a</sup> and George Z. Chen<sup>\*a,b</sup>

<sup>a</sup> Energy and Sustainability Research Division, Faculty of Engineering, The University of Nottingham, Nottingham NG7 2RD, UK; <sup>b</sup> International Academy of Marine Economy and Technology, The University of Nottingham Ningbo China, Ningbo, Zhejiang 315100, P. R. China.  
E-mail: [george.chen@nottingham.ac.uk](mailto:george.chen@nottingham.ac.uk)

Carbon nanotubes (CNTs) are one of the most studied and promising nano-fillers to enable the formation of polymeric composites with enhanced and improved functionalities. For example, composites of CNTs and electronically conducting polymers (ECPs, such as polypyrrole, PPy, and polyaniline, PAN) can offer superior performances in supercapacitors [1,2]. Perhaps the biggest challenge for ECP-CNT composite based supercapacitors to penetrate the energy markets is the fairly high cost/performance ratio that results from the current high market price of CNTs as raw materials. Therefore, it would be financially necessary to consider recovering the CNTs from their ECP composites in spent supercapacitors. Moreover, for implementing responsible innovation [3], the ECP-CNT composites in the spent supercapacitors should not be released to nature with respect to their potential health and environmental impacts.

It is demonstrated in this work that clean recovering of CNTs from ECP-CNT composites can be achieved by selective oxidation using Fenton's reagent ( $\text{H}_2\text{O}_2 + \text{Fe}^{2+}$ , pH=3) that completely mineralizes the ECP, but leaves the nanotubes intact (**Fig.1b**). In our tests of the Fenton oxidation, ECP-CNT composites progressively lost their redox activity (**Fig.1c**) and showed a drastic increase in charge transfer resistance.  $\text{CO}_2$  and  $\text{N}_2$  as degradation products of ECPs were also detected by gas chromatography. Importantly, it was found through characterization via various analytical techniques that the Fenton recovered CNTs (FRCNTs) were the major constituent in the solid residuals observed after the oxidation. Furthermore, in the cyclic voltammetric investigation on the electro-activity, the FRCNTs exhibited similar redox activity and comparable specific capacitance to the original CNTs, permitting the reuse for preparing a composite with PPy (**Fig.1d**).

In general, the selective Fenton oxidation to the ECPs coated on individual CNTs is a new and interesting concept, which is believed to be the first example of the CNT recovery from their polymer composites. This work may significantly improve the sustainability and competitiveness of supercapacitors for boosting commercialization.

**Fig.1.** (a,b) TEM images of (a) as-prepared PAN-CNT and (b) its Fenton oxidation product. (c,d) CVs of (c) PAN-CNT in 1.0 mol/L HCl recorded at the indicated time for immersion in the Fenton's reagent ( $[\text{H}_2\text{O}_2]/[\text{Fe}^{2+}]=100$ ,  $[\text{Fe}^{2+}]=1.0$  mmol/L), and (d) PPy-FRCNT and PPy-CNT in 0.5 mol/L KCl.

# Action Mechanism of Quaternary Ammonium Compound in the Electroreduction of Oxalic Acid to Glyoxylic Acid

Xinsheng Zhang, Ling Jin, Dongfang Niu, Wei-Kang Yuan

State Key Laboratory of Chemical Engineering, East China University of Science and Technology  
130 Meilong Road, Shanghai 200237, P.R. China  
[xszhang@ecust.edu.cn](mailto:xszhang@ecust.edu.cn)

Glyoxylic acid is an important intermediate in the perfumery, pharmaceutical and fine chemical industries. Production of glyoxalic acid by electroreduction of oxalic acid solutions has been investigated by many researchers<sup>[1-2]</sup>. Good yields of glyoxylic acid were reported with lead as the cathode material. But the key problem for commercializing the process is the cathode deactivation, the current efficiency and the reaction selectivity decrease dramatically throughout the operation. The cathode deactivation is not uncommon in electroreduction, such as dimerization of acetone to pinacol and electrohydrodimerization of acrylonitrile to adiponitrile<sup>[3]</sup>. There have been a few methods suggested for this problem<sup>[4]</sup>, e.g., washing the cathode with a dilute nitric acid, producing new apparent surface with electroplate, and mechanically cleaning the cathode surface. Unfortunately, all these are not considered as well acceptable by the industry. The adding additive (quaternary ammonium compound) into the catholyte was found to be the best way to keep the cathode from deactivation.

There are two major factors to decrease the current efficiency: increasing concentration of glyoxylic acid and decreasing activation of electrode, not single factor of cathode deactivation. It was also found that the electrode deactivation are affected by two reasons which being the higher concentration of glyoxylic acid and electrodeposition of a few metals of lower hydrogen overpotential on cathode.

When additives were added into electrolyte, the deactivation of cathode had not occurred in commercial model process. We found that the quaternary ammonium compounds can inhibit electrodeposition of metals ion on lead cathode to prevent from electrode deactivation, but also they inhibit evolution of hydrogen and inhibit electroreduction of oxalic acid. In another words, all reactions on cathode were depressed while electrolyte contained additives.

How do these additives act on electrode to increase current efficiency of glyoxalic acid? In fact, the additives could not only increase the mass transfer rate of oxalic acid from solution to electrode surface, but also accelerate desorption of glyoxylic acid from electrode surface, owing to tetraalkylammonium cations being formed ion pair with anions of glyoxalic acid or oxalic acid. So, we was put forward that the mechanism of phase transfer electrocatalysis of quaternary ammonium compound acted on cathode (see Fig. 1).

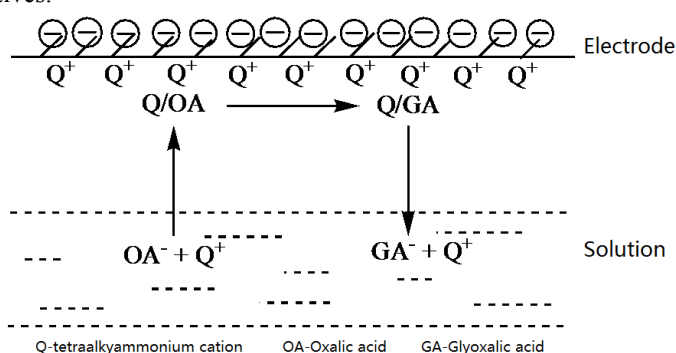

Fig. 1 Mechanism of Phase Transfer Electrocatalysis of Quaternary Ammonium Compound on Cathode

# Electrochemistry of Atomically Precise Metal Nanoclusters

Dongil Lee

*Department of Chemistry*

*Yonsei University*

*Seoul 120-749, Korea*

*dongil@yonsei.ac.kr*

Atomically precise metal nanoclusters containing a few to a few hundreds of atoms have been the focus of recent investigations because of their novel electronic, optical, and catalytic properties. They appear to represent the bulk-to-molecule transition region where electronic band energetics yield to quantum confinement effects and discrete electronic states emerge. I will firstly present recent advances in the synthesis of atomically precise gold nanoclusters and their size-dependent electrochemical and optical properties. Secondly, syntheses and characterizations of Au<sub>25</sub> nanoclusters doped with Pt and Pd will be presented. Electrochemical investigations of the doped nanoclusters showed that redox potentials of gold nanoclusters are significantly altered by doping with foreign metal atoms. Dramatic catalytic effect was observed for the reduction of azobenzene with gold nanoclusters doped with Pt and Pd. This effect can be ascribed to the doping-induced tuning of the redox potentials and enhanced electrocatalytic activity of the doped gold nanoclusters.

# Influence of Cations on the Control of the Multiple Redox States of Fullerene at the Ionic Liquid Electrochemical Interface

Precise control of the multiple redox states of organic molecules is one of the key technologies to realize high-efficient single-molecular electronic devices and organic rechargeable batteries. Fullerene has been expected to be a promising material due to its excellent electron accepting ability. Electrochemistry of fullerene films was investigated in several organic solvents. However, the control of the six redox states of fullerene was difficult because of the high solubility of fullerene anions in organic solvents. Recently, we succeeded in controlling the six redox reactions of fullerene at room temperature by using ionic liquids (ILs) [1]. In this study, we report the effect of the cations of ILs on the redox potentials of fullerene.

Tributylmethylammonium bis(trifluoromethylsulfonyl)imide ([N<sub>1,4,4,4</sub>][TFSI]), 1-butyl-1-methylpyrrolidinium bis(trifluoromethylsulfonyl)imide ([C<sub>4</sub>mpyr][TFSI]), 1-butyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide ([C<sub>4</sub>mim][TFSI]), triethylsulfonium bis(trifluoromethylsulfonyl)imide ([S<sub>2,2,2</sub>][TFSI]) were used. Prior to each experiment, Au(111) electrodes were annealed in a hydrogen flame, and then cooled down. The fullerene thin films were prepared by casting 50  $\mu$ M either C<sub>60</sub> or C<sub>70</sub> benzene solution onto a freshly-annealed Au(111) electrode. The electrochemical behavior of fullerene-modified Au(111) electrodes were investigated by cyclic voltammetry (CV) and differential pulse voltammetry (DPV).

Fig. 1 shows typical cyclic voltammograms of the fullerene-modified Au(111) electrodes in [C<sub>4</sub>mpyr][TFSI]. A clear difference could be observed between the first cathodic scan and subsequent scans, suggesting that overpotential is required to generate fullerene anions during the first cathodic scan. Each redox current gradually decreased with continuous scans, indicating the dissolution of fullerene anions into [C<sub>4</sub>mpyr][TFSI]. Table 1 shows the redox potential of C<sub>x</sub><sup>n-</sup>/C<sub>x</sub><sup>(n-1)-</sup> (C<sub>x</sub> = C<sub>60</sub>, C<sub>70</sub>, n = 1-6) ( $E_{n-(n-1)}$ ) in the ILs evaluated by DPV. The redox potentials were dependent on IL cations. Three or four redox couples of fullerene could be found in both [C<sub>4</sub>mim][TFSI] and [S<sub>2,2,2</sub>][TFSI] due to the low cathodic stability of [C<sub>4</sub>mim]<sup>+</sup> and [S<sub>2,2,2</sub>]<sup>+</sup>. For [C<sub>4</sub>mpyr][TFSI] and [N<sub>1,4,4,4</sub>][TFSI], the six redox couples of fullerene were observed. The average peak separation between any two successive redox potentials ( $\Delta E_{\text{ave}}$ ) increased in the order of [C<sub>4</sub>mpyr][TFSI] ( $\Delta E_{\text{ave}}$  = 380  $\pm$  10 mV) < [N<sub>1,4,4,4</sub>][TFSI] ( $\Delta E_{\text{ave}}$  = 450  $\pm$  20 mV).  $E_{6-5}$ ,  $E_{5-4}$ ,  $E_{4-3}$ , and  $E_{1-0}$  for C<sub>70</sub> in the ILs shifted to more positive potential than those for C<sub>60</sub>. These results indicate that the multiple redox states of fullerenes are controlled by not only the wide electrochemical potential window of ILs but also the strength of the interaction between fullerene and IL cations.

Fig. 1. CV profiles of (a) C<sub>60</sub>- and (b) C<sub>70</sub>-modified Au(111) electrodes in [C<sub>4</sub>mpyr][TFSI]. Scan rate: 100 mV s<sup>-1</sup>.

# Selective Electrochemical Fluorination of Organic Molecules and Macromolecules Using Poly(HF) Salt Ionic Liquids

Toshio Fuchigami and Shinsuke Inagi

Department of Electronic Chemistry, Tokyo Institute of Technology,  
Nagatsuta, Midori-ku, Yokohama 226-8502, Japan  
fuchi@echem.titech.ac.jp

Organofluorine compounds are highly useful for our daily life. Fluorinated organic molecules and macromolecules are of much importance as new types of pharmaceuticals, agrochemicals, and functional materials. In order to prepare organofluorine compounds, fluorinated building blocks and chemical fluorination have been mainly employed, however, the former is limited and the latter requires hazardous and/or explosive fluorination reagents. Therefore, we have developed selective electrochemical fluorination using poly(HF) salt ionic liquids [1-4] and metal fluorides [5,6]. Our fluorination method is promising from a viewpoint of green chemistry because any hazardous reagents are not required and fluorination can be achieved in one step without leaving groups. In this talk, we focus on selective electrochemical fluorination of various heterocyclic compounds as well as conducting polymers [1,7,8].

# Transition Metal $\alpha$ -Diimine Carbonyl Complexes for Electrocatalytic CO<sub>2</sub> Reduction

Joanne Tory, František Hartl

University of Reading

Department of Chemistry, University of Reading, Whiteknights Reading RG6 6AD, UK

j.tory@reading.ac.uk

There is substantial interest in the catalytic reduction of CO<sub>2</sub> to form products that are useful for energy storage and organic synthesis. In order to design more efficient catalysts, it is important to understand how the experimental conditions and molecular structure affect the catalytic activity of the system. We have studied a range of complexes related to the well-known [Re(CO)<sub>3</sub>(bpy)X] (bpy = 2,2'-bipyridine) [1] catalyst precursors using IR and UV-Vis spectroelectrochemical techniques. Reaction mechanisms and catalytic activity have been investigated for systems including the osmium complexes *trans*-(Cl)-[Os<sup>II</sup>(CO)(bpy)(PrCN)Cl<sub>2</sub>] (PrCN = butyronitrile) and *mer*-[Os<sup>III</sup>(CO)(bpy)Cl<sub>3</sub>] [2], the Group 6 dicarbonyl allyl complex [Mo<sup>II</sup>(CO)<sub>2</sub>(allyl)(bpy)(NCS)] [3], and [Mn(CO)<sub>3</sub>(iPr-DAB)Br] (iPr-DAB = *N,N'*-diisopropyl-1,4-diazabuta-1,3-diene) [4] which contains a non-aromatic  $\alpha$ -diimine ligand. We have also shown that the choice of solvent and working electrode can have a significant impact on the efficiency of electrocatalysis for the Group 6 complexes [M(CO)<sub>4</sub>(bpy)] (M = Cr, Mo, W). [5]

Here we will present a range of Group 7 complexes of the type [M(CO)<sub>3</sub>( $\alpha$ -diimine)X] (M = Mn, Re) with  $\alpha$ -diimine ligands such as 4,4'-bis(hydroxymethyl)-2,2'-bipyridine, 3,3'-dihydroxy-2,2'-bipyridine and *N,N'*-dimethylglyoxime that feature labile protons which may enhance the catalytic activity of the complexes and promote proton-coupled electron transfer. Combined chemical deprotonation and spectroelectrochemical experiments show that the reduction mechanisms of these complexes may be affected by reductive deprotonation of the  $\alpha$ -diimine ligands. Electrocatalysis is observed in the presence of CO<sub>2</sub> for both the rhenium and manganese complexes without addition of Brønsted acid.

Figure 1. [Mn(CO)<sub>3</sub>(dgmH<sub>2</sub>)Br] in THF/Bu<sub>4</sub>NPF<sub>6</sub>: Cyclic voltammetry (left), and IR spectroelectrochemistry showing reduction to [Mn(CO)<sub>3</sub>(dgmH)Br]<sup>-</sup> (↑) within an OTTE cell (right).

# Electrochemiluminescence of Quantum Dots and Clusters

Zhifeng Ding

*Department of Chemistry, The University of Western Ontario, London, ON N6A 5B7*

*zfding@uwo.ca*

Electrochemistry studies relations between electric work and chemical reactions, while photoelectrochemistry investigates the conversion between electrons and photons in chemical processes. Our lab at Western focuses on 4 research themes: scanning electrochemical microscopy of live cells, ionic liquids as novel electrolytes, electrochemiluminescence (ECL) and solar cells. Herein, we demonstrate our progresses on ECL of some nanocrystals.

ECL is the process in which electrogenerated radicals form excited species that emit light without the need for an external light source. ECL is a powerful analytical technique that is fast, highly sensitive and selective, requires low quantity and is cost effective. Herein, we illustrate our investigation on ECL of Au clusters and PbS nanocrystals in the near-infrared (NIR) region by combining conventional ECL detection with spectroscopic techniques to gain insights into thermodynamic and kinetic origins. Generating ECL light in the NIR is especially important for bioimaging applications.

# Electron-transfer Induced Reactions in Ru and Sn Complexes with Biological Activity

M. Fátima C. Guedes da Silva

*Centro de Química Estrutural, Instituto Superior Técnico, Universidade de Lisboa, Av. Rovisco Pais, 1049-001, Lisboa, Portugal*  
[fatima.guedes@tecnico.ulisboa.pt](mailto:fatima.guedes@tecnico.ulisboa.pt)

Bond cleavage and/or formation often constitute fundamental steps in chemical reactions, and electrochemical methods can be conveniently applied to induce them by electron-transfer. Electrochemistry can not only induce chemical reactivity but also investigate the kinetics and mechanisms involved. Theoretical studies combined with experimental electrochemical results can provide an interpretation and rationalization by disclosing possible products, intermediates and pathways towards the establishment of the mechanisms.

Metal-based drugs 'activated by reduction' have become popular with platinum and ruthenium compounds since various metal-complexes can exist in rather inert high oxidation states in aqueous solution but are more labile and active in reduced oxidation states. Quantitative kinetic analysis by digital simulation of the cyclic voltammograms in Ru(III) compounds allowed the establishment of the mechanism of the processes involved and enabled a correlation between the redox potential, the rate constant for solvolysis and cytotoxicity.

Moreover, electrochemical/theoretical studies on organotin(IV) complexes with hydroxamate (Figure) and carboxylate type ligands disclosed the involvement, in the reduction process, of structural rearrangements, specifically (i) the cleavage of Sn-O(ligand) bonds (generating coordinative unsaturation) and (ii) a geometrical *trans*-to-*cis* isomerization.

Discussion of biological significance of these results will be presented.

The antiproliferative properties of ferrocene, combined to the anti-estrogenic effect of the tamoxifen skeleton, have inspired the preparation of “ferrocifen” anticancer drug candidates in G. Jaouen’s group. The oxidation mechanism of compounds in the phenol series has been thoroughly investigated [1,2], allowing the identification of quinone methides as the metabolites responsible for the antiproliferative activity.

Here we present the electrochemical behavior of new ferrocenophanic compounds [3,4] and a ruthenocifen [5]. These molecules undergo distinct oxidative sequences which are discussed with respect to the mechanistic features established for ferrocifens.

# Break Junction under Electrochemical Gating: Fermi-level Tuning and Redox Manipulation

Wenjing Hong, Masoud Baghernejad, Cancan Huang, Thomas Wandlowski  
Department of Chemistry and Biochemistry, University of Bern, Bern, Switzerland  
Freiestrasse 3, CH-3012 Bern, Switzerland  
hong@dcb.unibe.ch / wenjinghong@gmail.com  
wa.dcb.unibe.ch/hong

Controlling charge transport through a single molecule connected to metallic electrodes remains one of the most fundamental challenges of single-molecule electronics. Break junction techniques are considered as ideal testbeds to investigate the charge transport on a single-molecule scale. An additional applied electrochemical gating in break junction experiments will provide a unique opportunity to manipulate the energy alignment and molecular redox processes on single-molecule scale. [1]

Using electrochemical STM based break junction technique, we systematically studied single-molecule electrochemical switches with different redox units, including ferrocene, naphthalenediimide, and tetrathiafulvalene. These studies indicate that the applied electrode potential can manipulate the redox states of single-molecule junctions, and the ON/OFF ratio of these switches between different redox states of the molecular junctions can reach up to four orders of magnitudes varying from different redox units.

On the other hand, the single-molecule conductance studies of 4,4-bipyridine, a redox-inactive molecule, demonstrate that the applied potential also aligns molecular frontier orbitals relative to the electrode Fermi-level, switching the molecule from an off resonance state to “partial” resonance. [2] A recent study of AQ-based molecules with the pyridine anchors showed that the single-molecule conductance could be controlled via both redox switching and Fermi level tuning by varying electrode potential. [3]

As a perspective, we will present our recent effort towards quantum interference effect single-molecule transistor under electrochemical gating.

Schematic to show the conductance tuning of an anthraquinone based single-molecule junction via energy alignment and redox manipulation

# The Effect of Ring-Size on the Anodic Oxidation of Cyclic Amides

James Y. Becker and Tatiana Golub

*Department of Chemistry, Ben-Gurion University of the Negev, Beer Sheva 84105,  
Israel*

*Email: becker@bgu.ac.il*

Anodic oxidation of N-alkylamides has been investigated extensively in the presence of various nucleophiles such as water, alcohols or carboxylic acids, to afford the respective  $\alpha$ -hydroxy, -alkoxy or -carboxy derivatives as final products, with **no** C-N or N-CO bond-breaking:

Interestingly, the anodic oxidation of N-arylamides [**lacking** 'H' atom(s) at  $\alpha$  position to 'N'] led to three types of bond cleavages, depending on the substituent attached to the aryl group [1].

The present work describes the electrochemical properties of three cyclic amides, N-acylazacycloalkanes (**I** - **III**) by both cyclic voltammetry and preparative electrolysis in methanol, at C anodes [2]. The outcome under various experimental

conditions (current density, electricity consumption, nature of supporting electrolyte) led to the formation of four major type of products:  $\alpha$ -methoxy- and  $\alpha,\alpha'$ -dimethoxy cyclic amides, and two cyclic **ene**amide derivatives. Their relative ratio was found to be highly dependent on the nature of the electrolyte and current density.

# Oxazaborine and Triazaborine Chromophores, Electrochemical and Theoretical Study

Jiří Ludvík<sup>1</sup>, Tomáš Mikysek<sup>2</sup>, Hana Kvapilová<sup>1</sup>, František Josefík<sup>2</sup>

<sup>1</sup>J. Heyrovský Institute of Physical Chemistry, ASCR, v.v.i., Dept. of Molecular electrochemistry;  
Dolejškova 3, 182 23 Prague 8, Czech Republic [jiri.ludvik@jh-inst.cas.cz](mailto:jiri.ludvik@jh-inst.cas.cz)

<sup>2</sup>University of Pardubice, Faculty of Chemical Technology, Studentská 573, Pardubice, CZ 532 10,  
Czech Republic

Unsaturated heterocyclic compounds containing a boron atom exhibit miscellaneous types of biological activity: antibacterial, antitumor, fungicidal, insecticidal, and herbicidal. Introduction of the boron atom into an organic molecule substantially changes its electronic – and redox – characteristics, which opens the way to the construction of optoelectronic materials for molecular electronics based on organic molecules. Borine-based materials could be thus used for organic light-emitting diodes (OLEDs).

The present contribution describes electrochemical properties of a series of newly synthesized compounds based on triazaborine core [1]. Their formation is based on a rearrangement of the oxazaborine [2] heterocycles as stable precursors. The studied molecules are bearing different donor and acceptor substituents changing and "tuning" their properties. Their reducibility and oxidizability were electrochemically investigated and the experimental data were correlated with quantum chemical calculations. The main attention has been paid to the investigation of the first oxidation and first reduction process of such compounds using cyclic voltammetry, rotating disk voltammetry and polarography.

In the homologous series of triazaborines the first reduction proceeds as a one-electron reversible process localized at the  $-N=C=N-$  part of the central heterocycle being in conjugation with the attached carbonyl. The first oxidation of triazaborines proceeds as a two-electron irreversible process, most probably of the ECE type, localized at the negatively charged boron atom and surrounding unsaturated structures including the substituted phenyl ring.

For better understanding of the relationship between the structure and redox properties, the Linear Free Energy relationship (LFER) approach using sigma (para) constants of Hammett type was applied, the oxidation and reduction centers were localized, the difference between  $E(\text{ox})$  and  $E(\text{red})$  was correlated with the HOMO-LUMO gap and with the longest-wavelength absorption bands taken from UV-vis spectra. The experimentally determined oxidation and reduction centers were compared with the calculated optimized structures and position of the frontier orbitals. The above presented interpretations were confirmed and the anomalous cases were elucidated.

# Electrochemically Induced Friedel-Crafts Arylation of Chalcone Epoxides and Enamides by Organic Redox Mediators

Chengchu Zeng, Nanling Lu, Longji Li

College of Life science & Bioengineering, Beijing University of Technology

Beijing 100124, China

zengcc@bjut.edu.cn

**Abstract:** Cation radical or anion radical, generated from electron transfer of a neutral organic molecule with an in-situ formed active species of a redox catalyst, is very active and readily undergo various chemical transformation, including cleavage, coupling and substitution reaction.<sup>1</sup> Herein, we will report two examples: 1) the indirect anodic oxidation of chalcone epoxides in the presence of electron-rich heteroarenes mediated by a triarylimidazole as a redox mediator,<sup>2</sup> and 2) Friedel-Crafts arylation of enamides induced by electrochemically generated triphenylamine cation radical via ex-cell electrolysis.<sup>3</sup> Cyclic voltammetry (CV) and controlled potential electrolysis was employed to explore their possible reaction mechanisms. Noteworthy, only catalytic amount of charge was required for the two types of reaction, which suggests that a chain reaction occurs upon initiation of a redox catalyst.

Scheme 1. Electrochemically Induced Friedel-Crafts Arylation of Chalcone Epoxides and Enamides.

e-mail address: [wenrong.yang@deakin.edu.au](mailto:wenrong.yang@deakin.edu.au)

We describe an alternative electrochemical technique to monitor single covalent bond formation in real-time using nanoparticle-electrode collisions. The method is based on recognising the redox current when MP-11 functionalised graphene nanosheets collide with Lomant's reagent modified gold microelectrode. The amplified redox current reflects directly single-molecule attachments in the presence of MP-11 functionalised graphene nanosheets, attached covalently through the amino functionalities of the polypeptide chain, prepared by depositing Lomant's reagent, 3,3'-dithiodipropionic acid di(N-succinimidyl ester) on the electrode surface for self-assembled monolayers (SAMs) on gold electrodes. The average number of covalent bonds is in the range of  $155 \pm 30$  on a single nanosheet. This facile and highly sensitive monitoring method can be useful for investigating the fundamental of single-molecule reactions.

Figure 1. Schematic of monitoring covalent bond formation. (a) Non covalent bond (Electrostatic interaction), (b) Covalent bond. The amplified redox current from MP-11 can be monitored. An amino covalent bond forms when MP-11 functionalised graphene nanosheets reach Lomant's reagent (SAMs) modified gold electrode and stick on the SAMs. The amplified redox current from MP-11 was detected.

# Tunable Peptide-Based Molecular Wires: Experimental Evidence and Theoretical Insights

Jingxian Yu, John R. Horsley, and Andrew D. Abell

ARC Centre of Excellence for Nanoscale BioPhotonics (CNBP), School of Physical Sciences, The University of Adelaide, Adelaide, SA 5005, Australia  
Email: jingxian.yu@adelaide.edu.au

Electrochemical studies are reported on a series of peptides constrained into either a  $3_{10}$ -helix (**1-6**) or  $\beta$ -strand (**7-9**) conformation, with variable numbers of electron rich alkene containing side chains. Peptides (**1** and **2**) and (**7** and **8**) are further constrained into these geometries with a suitable side chain tether introduced by ring closing metathesis (RCM). Peptides **1**, **4** and **5**, each containing a single alkene side chain reveal a direct link between backbone rigidity and electron transfer, in isolation from any effects due to the electronic properties of the electron rich side-chains. Further studies on the linear peptides **3-6**, confirm the ability of the alkene to facilitate electron transfer through the peptide. A comparison of the electrochemical data for the unsaturated tethered peptides (**1** and **7**) and saturated tethered peptides (**2** and **8**) reveals an interplay between backbone rigidity and effects arising from the electron rich alkene side-chains on electron transfer. Theoretical calculations on  $\beta$ -strand models analogous to **7**, **8** and **9** provide further insights into the relative roles of backbone rigidity and electron rich side-chains on intramolecular electron transfer. Furthermore, electron population analysis confirms the role of the alkene as a ‘stepping stone’ for electron transfer. These findings provide a new approach for fine tuning the electronic properties of peptides by controlling backbone rigidity, and through the inclusion of electron rich side-chains. This allows for manipulation of energy barriers and hence conductance in peptides, a crucial step in the design and fabrication of molecular-based electronic devices.

**Figure 1.** Molecular structures of  $3_{10}$ -helical (**1-6**) and  $\beta$ -strand peptides (**7-9**), and their electron transfer parameters. The three numbers listed in each bracket denote the surface concentration ( $\times 10^{-10} \text{ mole.cm}^{-2}$ ), formal potential (V vs AgCl/Ag) and electron transfer rate constant ( $k_{app}$ ) of the peptide shown above.

# **Electronic Structure Effects on Electron Transfer Controlled Hydrogen Bonding in Substituted Dinitrobenzene Electrogenenerated Anions As Receptors for 1,3-Diethylurea**

Carlos Frontana, Eduardo Martínez-González,  
*Centro de Investigación y Desarrollo Tecnológico en Electroquímica, SC  
Parque Tecnológico Querétaro S/N, Sanfandila, Pedro Escobedo, Querétaro,

cfrontana@cideteq.mx*

In Electron Transfer Controlled Hydrogen Bonding (ETCHB), switching molecules experiment changes in their reduction potential values as hydrogen bond donor species are added to the solution, and is the basis of operation of many molecular switches [1-3]. Therefore, a comprehensive understanding of the mechanistic routes that govern electron transfer in these systems would allow the design of devices with specific applications. In the case of complexes formed via ETCHB with electrogenerated anions from dinitrobenzene isomers [3-6], proton transfer reactions were also observed, diminishing the stability of these intermediates. In this work, a similar electrochemical analysis was performed using 1,3-diethylurea to avoid protonation; showing two sequential reversible voltammetric signals, from which  $K_b$  (binding constant) values were calculated. The experimental behavior suggest that the mechanistic routes for ETCHB depend on the relative position of the nitro groups within the molecule: For o- and p-dinitrobenzenes radicals, a reduction involving an  $E_{rev} E_{rev} C$  mechanism occurs while for with m-dinitrobenzene radicals, the reaction evolves by an  $E_{rev} C$   $E_{rev}$  route, leading also to changes by inductive effect caused by substituents present.

<sup>2</sup>Institute of Polymer Science and Engineering, National Taiwan University, Taipei 10617, Taiwan

\*E-mail: kcho@ntu.edu.tw

Electrochromism refers to the phenomenon that materials alter their optical characteristics reversibly through the manipulation of different potential biases. Among all electrochromic materials, the N, N-substituted bipyridiniums (also named as viologens (RVs)) receive much attention for their attracting optical characteristics change between their dication state ( $RV^{2+}$ , bleached) and cation-radical state ( $RV^{\bullet+}$ , colored). The working principle of a typical viologens based electrochromic device (ECD) coupled with a redox active material, such as ferrocene (Fc), is shown in Fig. 1. The long-term stability of viologens based ECD is suffered from the poor solubility of  $RV^{\bullet+}$ , which leads to the recrystallization of viologens, as well as the agglomeration of  $RV^{\bullet+}$  onto the electrode. Either the above two phenomena would result in an irreversible coloring/bleaching process, and decrease the stability of the ECD. Therefore, the retardation of the diffusion rate of the viologens via immobilization or size control through tuning the alkyl chain lengths on the pyridine, has been regarded as a feasible approach to prevent the decay of the ECD caused by the agglomeration. In this study, the relation between the alkyl chain length of viologens and their electrochromic performance were investigated by measuring the diffusion coefficients, optical transmittance responses, and cycling stabilities of the viologens based ECDs. In Fig. 2, the apparent diffusion coefficients ( $D_{app}$ ) of 0.02 M methyl viologen (MV), ethyl viologen (EV), heptyl viologen (HV), and octadecyl viologen (OV) in pertinent ECDs coupled with 0.02 M redox couple Fc, were obtained by chronoamperometry and calculated by Cottrell equation. The apparent diffusion coefficients of these ECDs decrease with longer length of alkyl chain of viologens would elucidate the relation between alkyl chain length of viologens and their electrochromic performance. The agglomeration of viologens during operation was also investigated by an electrochemical quartz crystal microbalance (EQCM).

## Introduction

Non-Pt-based cathode catalysts have been extensively investigated over the past several decades for the significance of cost reduction of polymer electrolyte fuel cells. Metallocomplex-type catalysts are considered as one prospective candidate of the cathode catalysts. Generally, the metallocomplex-type catalysts offer an isolated active metal center, which enables economical utilization of the metal. Besides this benefit, the fine tuning of the ligands would drastically effect on the electrochemical properties of the complexes.

We have focused on several bio-inspired copper complexes using pyridylalkylamine ligands as the models of copper containing enzymes. The electrochemical O<sub>2</sub> reduction reaction catalyzed by the complexes proceeded conjugated with the Cu<sup>II</sup>/Cu<sup>I</sup> redox pair by 4-electron manner in a neutral aqueous solution<sup>1</sup>. Although the copper complexes were found to show O<sub>2</sub> reduction activity in an aqueous solution, there is room to improve the activity. In this study, the copper complexes including a series of ligands substituted by carboxyl group were synthesized, and the substituent effects on their electrochemical properties and O<sub>2</sub> reduction activity were investigated at various pH.

## Experiments

The Cu<sup>II</sup> complexes supported by bmpa (bis(2-pyridylmethyl)amine, [1]) and their carboxyl derivatives (*o*-derivative [1-*o*], *m*-derivative [1-*m*], and *p*-derivative [1-*p*]) were synthesized according to the reported procedures with a slight modification<sup>2</sup> (Fig. 1).

Voltammograms under quiescent conditions were taken in 10 mM Britton-Robinson buffer solution (CH<sub>3</sub>COOH, H<sub>3</sub>PO<sub>4</sub>, H<sub>3</sub>BO<sub>3</sub>, supporting electrolyte: 10 mM Na<sub>2</sub>SO<sub>4</sub>) containing 0.3 mM of the copper complex. All measurements in this study were performed using glassy carbon as a working electrode, Pt coil as a counter electrode, and Ag|AgCl|KCl(sat.) as a reference electrode.

## Results and discussion

Cyclic voltammograms of the copper complex with each of the ligand (Cu-[1], Cu-[1-*o*], Cu-[1-*m*], and Cu-[1-*p*]) under Ar atmosphere at pH 7.0 show reversible voltammograms derived from Cu<sup>II</sup>/Cu<sup>I</sup> redox pair. This result indicates that the redox reaction is less inhibited by the substitution of the carboxyl groups. It also be founded that *o*-substitution causes the negative shift of the redox potential (*E*<sup>o</sup>) though *m*-, or *p*-substitution causes the positive shift of *E*<sup>o</sup>. The negative charge of *o*-carboxy group would give special electronic effect on the copper center due to adjacency.

The *E*<sup>o</sup>-pH diagram of Cu-[1], Cu-[1-*m*], and Cu-[1-*p*] observed substantially negative shift of the redox potential with the increase in pH. Contrary to that, that of Cu-[1-*o*] was less sensitive to the change of pH, which indicates hydroxide ions can be less likely to coordinate to Cu-[1-*o*]. It was thought to be advantageous for the O<sub>2</sub> reduction reaction.

The onset potential of electrochemical O<sub>2</sub> reduction activity of Cu-[1-*o*] tended to be slight higher than the other complexes. It would be attributed to higher reducing activity of Cu<sup>I</sup>-[1-*o*].

# Investigation of Electrode Reaction at Well-Defined Electrochemical Interfaces in Ionic Liquids

Miangang Li, Li Chen, Yunxin Zhong, Jiawei Yan, Bingwei Mao\*

*State Key Laboratory for Physical Chemistry of Solid Surfaces, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen, 361005*  
*bwmao@xmu.edu.cn*

Room-temperature ionic liquids are a class of new solvents with low vapor pressure, wide electrochemical window, good ionic conductivity and thermal stability, and thus find a wide range of applications in various fields. However, owing to the high concentration, large size and asymmetric structure of the ions, the structure and kinetics at the electrochemical interfaces in ionic liquid are very different from those of conventional solvents. Substantial theoretical and experimental progresses have been achieved, which reveals that electric double layers in ionic liquids have unique layered structures<sup>[1,2]</sup>. However, investigations of the electrode reactions taking place in the double layer region in ionic liquid are very limited. Experiments and molecular dynamics simulations of redox reactions at the interface have been conducted, and kinetic behaviors have been analyzed using Butler-Volmer or Marcus-Hush model to estimate the charge transfer factor  $\alpha$  and reorganization energy  $\lambda$ <sup>[3]</sup>. But almost all of the works used microelectrodes as the working electrodes, and the influences of the detailed double layer structures on the reaction kinetics are far from clear.

In this work, we present an investigation of electrode reaction at well-defined electrochemical interfaces formed by Ag single-crystal electrodes with ionic liquids. Ag(111) single crystal electrode is chosen as the working electrode, whose double layer structure and adsorption of EMITFSI ionic liquids can be determined independently by AFM and STM, respectively. Fast voltammetry, double potential step chronoamperometry and electrochemical impedance spectroscopy are employed to study the kinetics of the electrode reaction. Together with the temperature-dependent measurements, kinetic parameters are obtained, and the influence of the double layer structure is discussed. The present work demonstrates the correlation of kinetics and structure at structurally well-defined electrochemical interface in ionic liquids.

This work was supported by the National Basic Research Program of China (2012CB932902, 2015CB251102) and the National Natural Science Foundation of China (21033007).

# Original Porphyrin – Polyoxometalate Copolymers: Application for the Photocurrent Generation

Zhaohui HUO, I. Azcarate, E. Lacôte, B. Hassenknopf, C. Bucher, L. Ruhlmann

Laboratoire d'Electrochimie et de Chimie Physique du Corps Solide, Université de Strasbourg, 4 rue Blaise Pascal, 67000, Strasbourg, France

zhaohui.huo@etu.unistra.fr, lruhlmann@unistra.fr

Polyoxometalates (POMs) are metal-oxygen cluster anions constituted of metal elements in their highest oxidation state which can undergo reversible and multi-electron photoredox processes. Unfortunately, POMs can be excited (POM\*) only under UV irradiation. Chromophore-POMs could offer a way to overcome part of this problem. Various type of electrostatic or covalent POM-porphyrin copolymeric films were synthesized. First, poly-zinc octaethylporphyrin/viologen/POM films were obtained through incorporating various type of POM<sup>n-</sup> (Preyssler, Keggin, etc...) onto the copolymer poly-zinc octaethylporphyrin/viologen (poly-ZnOEP-V<sup>2+</sup>) obtained by electro-oxidation of the macrocycle in the presence of 4,4'-bipyridine [1]. Then, by metathesis reaction, the (partial) exchange of the initial counter ion PF<sub>6</sub><sup>-</sup> by the POM<sup>n-</sup> ([SiW<sub>12</sub>O<sub>40</sub>]<sup>4-</sup> or [NaP<sub>5</sub>W<sub>30</sub>O<sub>110</sub>]<sup>14-</sup>) gave the target copolymer poly-ZnOEP-V<sup>2+</sup>-POM<sup>n-</sup> (Fig. 1) [2]. Their formation was also studied by AFM and EQCM.

Fig 1. Left: formation of the copolymer poly-ZnOEP-Viologen (Poly-ZnOEP-V<sup>2+</sup>). Middle: AFM picture of poly-ZnOEP-V<sup>2+</sup> obtained after 25 iterative scans. Right: Cyclic voltammograms recorded during electropolymerization. The modified ITO electrode after soaking (a) 1 min and (b) 10 min in aqueous solution containing Keggin type POM ([SiW<sub>12</sub>O<sub>40</sub>]<sup>4-</sup>).

Second, hybrid POM-porphyrin copolymeric films were directly obtained by the electro-oxidation of ZnOEP in the presence of different type POMs (Lindqvist, Keggin and Dawson) bearing two pyridyl groups (POM(py)<sub>2</sub>) [3]. Fig. 2 shows one example of electropolymerization of conjugated Dawson-type POM-porphyrin copolymers. Their photovoltaic performances have been investigated by photocurrent transient measurements [4] (Fig. 3). The impedance measurement under visible illumination will be also presented and compared with the efficiency for the photocurrent generation.

# Electrosynthesis Processes Based on Oxidative Couplings of Porphyrins for the Formation of Supramolecular Assemblies

L. Ruhlmann

Laboratoire d'Electrochimie et de Chimie Physique du Corps Solide, Université de Strasbourg, 4 rue  
Blaise Pascal, 67000, Strasbourg, France  
lruhlmann@unistra.fr

Porphyrins and porphyrin-containing materials have attracted considerable attention in recent last decades. For instance, in the photosynthesis process, chlorophyll possesses functions are able to convert sunlight energy into chemical energy. A number of researchers have attempted to construct artificial light-harvesting systems that provide important contributions not only to understand the natural systems but also to mimic nature in creating new efficient light-harvesting systems for energy conversion.

In this context, the presentation will be devoted to multiporphyrin systems obtained by electrosynthesis from oxidation of porphyrin macrocycle. Oxidation of the  $\pi$ -ring of a porphyrin macrocycle proceeds *via* two one-electron steps generating the  $\pi$ -radical cation and the dication, species known to be very reactive. Indeed, these cationic species have an electrophilic character, leading as first type of reactivity to reactions with nucleophilic compounds (Nu = pyridinyl or phosphine group). Thus, nucleophilic substitutions can be performed onto free carbons (carbons with one H in *meso* or  $\beta$  positions) of porphyrin macrocycles, allowing not only an easy grafting of substituents onto porphyrins, but also the synthesis of oligomers of porphyrins by using compounds having two nucleophilic sites (4,4'-bipyridine, diphosphine, etc.) as spacers between macrocycles (Fig. 1).<sup>[1]</sup> The second type of reactivity based on

oxidized porphyrins relies on couplings of oxidized porphyrins with each other, leading again to oligomers of porphyrins, but with direct links, *i.e.*, without spacers between macrocycles in this case. Even if classical oxidants can be used to perform such reactions, the advantage of these synthetic methods is that it is possible to perform them by an electrochemical pathway, since oxidized porphyrins can also be electrochemically obtained. Thus, the reactivity of porphyrin  $\pi$ -radical cations and dications, easily obtained by an electrochemical pathway, offers a new and facile synthesis method for obtaining multiporphyrin systems.<sup>[2]</sup>

Fig 1. Electrosynthesis scheme of the oligomers with pyridinium spacers (see Ref. 1h).

## Abstract:

Understanding the electronic properties of single peptides is not only of fundamental importance, but it is also paramount to the realization of peptide-based molecular electronic components. Electrochemical and theoretical studies are reported on two  $\beta$ -strand-based peptides, one with its backbone constrained with a triazole-containing tether introduced by Huisgen cycloaddition (**1**) and the other a direct linear analogue (**2**). Density functional theory (DFT) and non-equilibrium Green's function were used to investigate conductance in molecular junctions containing peptides **3** and **4** (analogues of **1** and **2**). While the peptides share a common  $\beta$ -strand conformation, they display vastly different electronic transport properties due to the presence (or absence) of the side-bridge constraint and the associated effect on backbone rigidity. These studies reveal that the electron transfer rate constants of **1** and **2**, and the conductance calculated for **3** and **4**, differ by approximately one order of magnitude, thus providing two distinctly different conductance states and what is essentially a molecular switch. A definitive correlation of electrochemical measurements and molecular junction conductance simulations is demonstrated using two different charge transfer techniques. This study furthers our understanding of the electronic properties of peptides at the molecular level, which provides an opportunity to fine-tune their molecular orbital energies through suitable structural manipulation.

**Figure:** Vast differences in the electronic transport properties of the two novel peptides (a) constrained and (b) linear, measured by electrochemical techniques as well as molecular junction conductance simulations, provide two distinctly different conductance states, in what is essentially a molecular switch.

# Synthesis of a $\pi$ -conjugated porphyrin polymer film on electrode by electrooxidation of 5,15-di(4-aminophenyl)-10,20-diphenylporphyrinatozinc(II)

Porphyrins have been a well-known family exhibiting interesting photochemical and electrochemical properties, that can be fine-tuned by introducing substituents on the porphyrin ring or simply introducing various kinds of metals at the center [1]. Porphyrin polymer films on electrode have been prepared by both electrooxidation and electroreduction methods [2], and the electropolymerized porphyrin films have been utilized as photosensitizer, electrochromic sensor, and sensitizer in dye-sensitized solar cells. In this research, we investigated the synthesis of a new  $\pi$ -conjugated porphyrin polymer film on glassy carbon (GC) and indium-tin oxide (ITO) by electropolymerization of 5,15-di(4-aminophenyl)-10,20-diphenylporphyrinatozinc(II) (**ZnP-1**). A plausible mechanism of the polymerization reaction is shown in Figure 1. When a consecutive potential scan between -0.7 V and 0.8 V vs.  $\text{Ag}^+/\text{Ag}$  was carried out in a 2 mM solution of **ZnP-1** in 0.1 M  $\text{Bu}_4\text{NClO}_4$ -dichloromethane at GC, an anodic wave at 0.546 V and a cathodic wave at 0.428 V increased, indicating formation of a redox active film on the electrode (Figure 2). The modified electrode thus formed showed a reversible redox reaction of surface-confined species, which were characterized using UV-Vis spectroelectrochemical measurements.

**Figure 1.** Schematic illustration of a proposed mechanism of the electrooxidative polymerization of **ZnP-1** on substrates.

**Figure 2.** Cyclic voltammogram for electropolymerization of **ZnP-1** (2 mM) by consecutive potential scans (from 1st to 50th cycles) in 0.1 M  $\text{Bu}_4\text{NClO}_4$ -dichloromethane at GC.

# Catalytic reduction of O<sub>2</sub> by ferrous hemin over formation of ferrous hemin-O<sub>2</sub> adduct

Jingyuan Chen, Wenwen Li, Koichi Aoki,  
*Department of Applied Physics, University of Fukui,*  
3-9-1 Bunkyo, Fukui, 910-8507 Japan  
jchen@u-fukui.ac.jp

Hemin, an iron porphyrin, functions as a carriage of dioxygen in mammalian respiration in the ferrous form. It works also as an electrochemical catalyst of the reduction of dioxygen by reproducing the ferrous form from the ferric one. Since the carriage requires stabilization of the dioxygen adduct, the catalytic reduction of dioxygen with the ferric form might hinder the stabilization. This work aims at finding the discrimination between the functions of the carriage and of the catalysis. A hint of the finding lies in the difference between the remarkable catalytic currents in high concentrations of hemin and negligibly small ones in very low concentrations. The catalytic current (Fig.1 (b)) at the hemin-coated electrode is confirmed to occur at the stoichiometry of two hemin molecules and one dioxygen molecule. When this stoichiometry is applied to the dioxygen adduct of hemin as an intermediate species of the catalysis, high concentrations of dissolved hemin should provide the catalytic current. Spectro-electrochemistry (Fig.2) demonstrates that ferrous hemin is not oxidized simply to the ferric form but is converted to other species, e.g. the dioxygen adduct.

**Fig.1** Voltammograms at the hemin-coated GC electrode in (a) deaerated and (b) aerated phosphate buffer solution, pH 7.4 for  $\nu = 0.1 \text{ V s}^{-1}$ . (c) is at the bare GC electrode in the aerated solution.

**Fig.2** UV-vis spectra of (a) hem( $\text{Fe}^{3+}$ ), (b) hem( $\text{Fe}^{2+}$ ) and (c) dioxygen-added hem( $\text{Fe}^{2+}$ ) for 30 s in the UV thin layer cell including 0.032 mM hemin + DMSO. The reduction was made at -0.6 V vs. Ag|AgCl for 10 min.

Electronic redox changes of thin films coupled with changes in absorption wavelengths or molar extinction coefficients are of interest, e.g., as smart windows, smart mirrors or smart curtains. Direct electrochromic devices are most promising. As an alternative to classical inorganic electrochromic layers like tungsten oxide, thin films of organic pigments and dyes like phthalocyanines are of interest as electrochromic layers because of their high molar extinction coefficients and a large change of color upon redox reactions allowing to use considerably thinner films and, hence, promising considerably faster switching within seconds rather than minutes [1].

In this work, thin homogeneous films (5-120 nm) of the electron deficient perfluorinated phthalocyanine F<sub>16</sub>PcCu and the perfluoroalkyl-substituted perfluorophthalocyanine F<sub>64</sub>PcCu have been prepared by physical vapor deposition onto ITO-glass and their redox characteristics in contact to aqueous solutions were studied. The films were readily reduced and re-oxidized at potentials slightly negative of the Ag/AgCl reference electrode confirming a significant stabilization of the produced anions by the electron-withdrawing fluorinated substituents. A significant color change accompanied the change of the molecular redox states. Electroneutrality of the films was ensured by (de-)intercalation of K<sup>+</sup>-counter ions upon reduction (re-oxidation). F<sub>64</sub>PcCu was reduced by one electron, F<sub>16</sub>PcCu by up to two, for thin films and slow charging rates. Steric hindrance of the fluorinated ligands influence the extent of intermolecular coupling. The perfluoroalkyl groups in F<sub>64</sub>PcCu thereby led to widely decoupled electronic states of the molecules in the thin films leading to facile diffusion of K<sup>+</sup>-counter ions in the films at, however, significantly reduced electrical conductivity of F<sub>64</sub>PcCu relative to F<sub>16</sub>PcCu. Time-resolved measurements served to analyze the interplay of the two mandatory transport processes. The difference in steric hindrance resulted in a change of the rate-limiting step. Thus, for films of F<sub>64</sub>PcCu the transport of electrons in the molecular films is rate-limiting, as opposed to counter ion diffusion in the case of F<sub>16</sub>PcCu. This switch underlines the importance of molecular structural parameters for the optimization of reaction rates in organic electrochromic thin films via intermolecular interactions.

## Tuning of charge transport in single molecule with the chemical and electrochemical methods

Cancan Huang, Wenjing Hong, Thomas Wandlowski  
Department of Chemistry and biochemistry, University of Bern  
Freiestrasse 3, CH-3012, Bern, Switzerland  
huangcancan1989@gmail.com

Molecular electronics targets the application of functionalized molecules as novel building blocks in electronics circuits. To reach this goal, understanding and tuning of charge transport in the single molecule comprise an essential prerequisite. We present the mechanical controllable break junction (MCBJ) and scanning tunneling microscopy break junction (STM-BJ) techniques to collect the charge transport information of the single molecules. To tune the charge transport effectively, we introduce the in situ chemical reaction and electrochemical gating methods.

1), The (benzodifuran) BDF - (oligo-(phenyleneethynylene)) OPE cruciform molecule are verified by single-molecule conductance measurement using MCBJ techniques with the conductance difference of more than one order of magnitude. Upon in-situ cleaving of the TIPS groups, the complete conversion from the M1-x junctions to M1-y junctions could be achieved. More importantly, the conductance pathway control via chemical tuning provides a unique flexibility in the modulation design, hence selective anchoring to electrodes.

2), We introduced the redox active unit ferrocene into A-shape molecule (shown above right). The electrochemical gating method based on the STM-BJ technique is used to control the state of iron ions to tune the charge transport properties of the single-molecule junctions.

# Structure-controlled Electrochemical Reduction of mono- and di-, nitro or nitroso Calix[4]arenes

[jiri.ludvik@jh-inst.cas.cz](mailto:jiri.ludvik@jh-inst.cas.cz)

The newly synthesized series of mono- and di-, nitro or nitroso calix[4]arenes has been investigated electrochemically. It was shown that besides the fundamental redox characterization, the electrochemical data contain also information about the space arrangement of the molecule as well as about dynamic 3D changes [1]. The interpretation is based on the comparison of observed electrochemical behaviour of homologous couples or triads taken from the studied series of compounds. Using the nitro- and nitroso group as a redox probes it was found that unsubstituted or *para*-nitro substituted *cone*-calixarenes are flexible, exhibiting in solution a periodic *pinched cone-pinched cone* interconversion, whereas the *1,3-alt*-conformation or any *meta*- substitution causes rigidity of the whole skeleton. All aromatic nitro- and nitroso groups in calixarenes appeared to be reducible at the same potential showing their electronic independency on the rest of the molecule [2].

In nanofluidic electrochemical sensors, zeptomole quantities of analyte molecules can be detected: redox-active molecules travel diffusively between two electrodes separated by a nanoscale gap. They are repeatedly oxidized and reduced, thus generating a highly amplified current per molecule. In these sensors, Brownian motion of minuscule analyte molecule numbers leads to considerable fluctuations in the Faradaic currents. These fluctuations can be explored by electrochemical correlation spectroscopy [1] and stochastic amperometry [2] to extract molecular properties, namely diffusivity and reversible adsorptivity, the latter being highly pronounced at the high surface-to-volume ratio of a nanochannel [3].

Nanofluidic sensors so far have mostly been used to detect prototypical ferrocenes. Here, we employ them to study 2,3,4-triferrocenylthiophene (2,3,4-Fc<sub>3</sub>-C<sub>4</sub>HS) [4] by stochastic amperometry and correlation analysis. This compound displays three well-resolved electrochemically reversible one-electron-transfer processes using [N<sup>n</sup>Bu<sub>4</sub>][B(C<sub>6</sub>F<sub>5</sub>)<sub>4</sub>] (0.1 M) as electrolyte in dichloromethane – also when undergoing redox cycling in a nanochannel. By setting both electrodes to different fixed potentials corresponding to the different waves, we can perform redox cycling between arbitrary redox potentials. Thus, for the first time, we use electrochemical nanogap sensors to study the effective diffusion coefficient *as a function of the redox state* of a molecule.

**Fig.** (a) Schematic cross-section of a nanogap sensor. (b) Cyclic voltammogram of 0.5 mM 2,3,4-Fc<sub>3</sub>-C<sub>4</sub>HS in the nanogap sensor (in 0.1 M [N<sup>n</sup>Bu<sub>4</sub>][B(C<sub>6</sub>F<sub>5</sub>)<sub>4</sub>] in dichloromethane). (c) Power spectral densities of 2,3,4-Fc<sub>3</sub>-C<sub>4</sub>HS undergoing redox cycling at different oxidation potentials.

*li.yang@angstrom.uu.se*

Organic electrode materials with high charge capacity, conductivity and cycling stability are appealing for electric energy storage application due to the limited mining resources of inorganic alternatives and their energy consuming production and recycling processes. Carboxyl compounds, e.g. diethyl terephthalate (DeT), show high charge capacity and have been used in lithium and sodium batteries. DeT and its analogues can be prepared from biomass and recycled easily by combustion. However, poor conductivity and cycling stability of this compound hinders its applications in energy storage systems. These problems can be solved by attaching the redox compound onto a conducting polymer (CP) backbone with good stability in organic solvents. Such combination could improve the stability of the material during cycling. More importantly, the CP backbone becomes electronically conducting upon n- or p-doping which could improve the electron transfer within the material and avoid the need for carbon additives in batteries.

Based on our previous matching studies between DeT and thiophene-based CPs, we have prepared a conducting redox polymer (CRP) with terephthalate as the pendant group and polythiophene as the backbone. Both n- and p-doping of the CP backbone could be distinguished in cyclic voltammograms and redox peaks of DeT were found to be located in the n-doping region of the CP. This is the first report, to our knowledge, that successfully achieves redox activity of pendant groups in an electronically conducting region of a CP backbone. Kinetic studies of the CRP showed high rate constants for both reduction and oxidation of terephthalate moieties. Diffusion limitation was not observed for a CRP polymer film with a thickness of tens of micrometers. Given their p-doping capabilities, terephthalate-substituted CRPs may be used as both anode and cathode materials for energy storage applications.

Surface-enhanced Raman spectroscopy (SERS) with high surface sensitivity and selectivity requires nanostructured substrates to promote localized or propagating surface plasmon (SP) mode, and therefore it had not been applied to study the processes taking place at atomically flat single crystalline surfaces of various electrodes. Since 2010, the invention of shell-isolated nanoparticle-enhanced Raman spectroscopy (SHINERS) has enabled SERS to study electrified single-crystal /electrolyte interfaces, but these studies have been limited into strong adsorption systems<sup>[1, 2]</sup>.

Very recently we utilized SHINERS to study the ordered and disordered adsorption of (bi)sulfate anions on Au single crystal electrode surfaces, aiming to reveal the interactions of the adsorbed molecules of different structure with surfaces. The potential-dependent SHINERS spectra on Au(111), Au(100) and Au(110) (Fig. 1) elucidate different adsorption behaviors on these surfaces with a distinct surface Raman feature from the adsorption of (bi)sulfate. The peaks in the low frequency region reveal the facet-dependent Au-O ( $\text{SO}_4^{2-}$ ) interaction, which is very difficult to be studied using other vibrational spectroscopies. The relevant DFT calculation is also performed to assign the spectral bands and explain the potential-dependency of the Raman features.

**Fig. 1.** SHINERS spectra of (bi)sulfate adsorption on (a) Au(111), (b) Au(100) and (c) Au(110) in 0.1 M  $\text{H}_2\text{SO}_4$ , laser power: 5 mW, collecting time: 100 s.

The present work further demonstrates that SHINERS could become a powerful tool to study fundamental issues of surface electrochemistry, not only strong but also weak interaction systems.

This work is supported by Natural Science Foundation of China (NSFC No. 21033007, 20973141).

# DFT Study of Surface Charging Effects on Oxygen Covered Pt(111)

Ali Malek, Mohammad J. Eslamibidgoli and Michael H. Eikerling

*Department of Chemistry, Simon Fraser University,  
8888 University Drive, Burnaby, BC, Canada V5A1S6  
e-mail: meikerl@sfu.ca*

Platinum plays an important role in catalysis and electrochemistry, and it is known that interaction of oxygen with Pt surfaces leads to the formation of platinum oxides and buckling of Pt surface atoms, which can affect the electrocatalytic reactivity[1]. Distribution of oxygen atoms and electronic charge density at the Pt-solution interface vary with the applied electrode potential. We use calculations based on density functional theory to investigate the various stages of oxidation of a Pt(111) surface. The system is modeled with a 5 layer slab within a  $3 \times 3$ ,  $4 \times 4$  and  $2\sqrt{3} \times 2\sqrt{3}$ -R30° supercell with atomic oxygen adsorbed on the Pt surface. Optimized configurations of the model system, are analyzed in view of oxygen adsorption energies, work function, average Pt atom displacement, surface charge density and dipole moment. It is found that below 50% coverage the favored surface configuration of adsorbed oxygen resides in *fcc* hollow sites. Additionally, the electronic density of states in *d*-orbitals of Pt atoms projected to the surface and sub-surface layer of Pt, and *d*-band center energies,  $\epsilon_d$ , will be analyzed as a function of the oxygen surface coverage. Effects of explicit water layers on oxide formation at the Pt surface will be discussed.

Rational design of interfacial structures for diverse applications – electrocatalysis, sensors, energy storage / conversion, optical devices and surface protection - has attracted huge research interest and synthetic methodologies have been developed for surface attachment of the relevant functionalities. Efficacy of the surface synthetic processes is generally established *via* structural and compositional probes. In the case of spectroscopic probes (e.g. FTIR, Raman, UV/visible), some *lateral* resolution is possible but the data are *vertically* integrated, so one does not know whether the functionality lies at the film/solution interface, within the film interior or at the electrode/film interface. In the case of imaging methods (e.g. SEM, STM, AFM), information is restricted to the external surface.

This motivates development of techniques that probe the interior of the film and do so with vertical spatial resolution. A technique that accomplishes this is neutron reflectivity (NR). The penetrating nature of neutrons permits *in situ* compositional and structural analysis of buried interfaces. Additionally, since the interaction of the neutrons is with the nuclei in the sample, the response is isotopically sensitive. This so-called "contrast variation" approach, most commonly implemented by H/D substitution (e.g. of the solvent), can provide unequivocal evidence of the spatial locations of film components, both the "fixed" species chemically bound to the electrode and the "mobile" species from solution that permeate the film.

While giving access to buried interfaces, the weak interaction of neutrons with the sample means that data acquisition times are long. Until recently, acquisition of a typical neutron reflectivity profile required several hours. While the spatial information was detailed and unique [1], observations were restricted to static conditions. As a first attempt to mimic *in operando* conditions, we used a boxcar averaging method to accumulate reflectivity profiles during repetitive potential cycles [2]. This reveals interesting departures from static conditions, but still requires long data acquisition times, is restricted to redox-stable materials and cannot be applied to single shot experiments, such as film deposition or dissolution.

A recent instrumental development, "event mode" data capture, involves recording of every neutron interaction with the surface. This permits setting of the averaging period (data "slices") post-experiment. When coupled with improvements in detector performance it decreases data acquisition times by approximately two orders of magnitude. This is consistent with dynamic electrochemical conditions that might be encountered in the operation of an electrochemical device or process. We now demonstrate this powerful new capability in the context of metal electrodeposition, dissolution and alloying involving single and multi-component films of Cu, Ag and Sn on Au electrodes exposed to choline chloride / hydrogen bond donor (ethylene glycol, urea) ionic liquid media.

NR measurements have been made for metal deposition and dissolution using different electrochemical control functions (potentiostatic, potentiodynamic and galvanostatic). We compare the NR responses for deposition of two metals simultaneously and sequentially; simplistically, these might be expected to generate a composite or alloy and a bilayer. In the latter instance, we compare the outcomes of deposition in either order. Indications of surface processes are given by surface imaging, by QCM nanogravimetric responses and by the electrochemical responses for film stripping. For example, the chronopotentiometric responses for galvanostatic stripping of Au/Ag/Cu and Au/Cu/Ag indicate access of Cu to the electrolyte in both cases. In the case of Au/Cu,Sn (in both combinations), alloy formation is indicated. NR data acquired under dynamic conditions (with event mode data capture) provide novel spatial insights into the dynamics of these deposition, alloying and dissolution processes.

# Mapping Oxygen Reduction at Individual Nanostructures Using High-Resolution Electrochemical-Topographical Imaging

Andrew J. Wain, Josh Lewis, and Mike A. O'Connell

*National Physical Laboratory  
Hampton Road, Teddington, United Kingdom, TW11 0LW  
andy.wain@npl.co.uk*

Electrochemical methods are essential for the development of new electroactive and electrocatalytic materials for emerging technologies such as sensors and energy conversion devices. Whilst macroscopic approaches such as cyclic voltammetry can provide detailed insights into electrokinetics and mechanism at the bulk or ensemble level, the information gleaned is spatially averaged and often fails to reveal how activity is distributed across the electrode surface. This information is vital in establishing structure-activity relationships, particularly for novel nanostructured materials that exhibit intrinsic heterogeneity at the smallest of scales.

Scanning electrochemical microscopy (SECM) provides a valuable approach to spatially resolved electrochemical characterization, and advanced hybrid techniques enable not only high-resolution electrochemical mapping, but simultaneous topographical imaging. Such dual function imaging allows one to pinpoint regions of high and low activity on the sample and correlate them with specific particles, structures or surface features.

This presentation will highlight recent developments in the high-resolution electrochemical and topographical imaging of nanostructured electrode surfaces. Focus will be on the combination of SECM with scanning ion conductance microscopy (SECM-SICM) through the development of double-barreled pipette probes comprising an open SICM barrel and a solid carbon SECM electrode. Unmodified probes allow electrochemical imaging of 150 nm diameter gold nanodisks using a simple reversible redox mediator whilst platinization of the carbon electrode adds greater functionality enabling oxygen reduction activity to be measured. This is demonstrated by mapping (i) competitive oxygen reduction and (ii) hydrogen peroxide generation at carbon electrodes decorated with platinum nanospheres and gold nanoaggregates. Individual particles are clearly resolved electrochemically and topographically, highlighting the potential of this technique to enable measurement of intrinsic electrokinetics at the single nanoparticle level.

# In-situ Study of Oxygen Reduction in DMSO Solution

Yu QIAO and Shen YE\*

Catalysis Research Center, Hokkaido University, Sapporo 001-0021, Japan

E-mail address: ye@cat.hokukai.ac.jp

Rechargeable Li-O<sub>2</sub> battery is regarded as one of the promising candidates for the next generation power sources of electrical vehicles because of its high theoretical energy density [1]. However, many fundamental issues about the reaction mechanism in the Li-O<sub>2</sub> battery, which are extremely important to understand and develop the novel battery system, are still unclear [2-4]. In the present work, mechanisms for the oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) on a flat gold electrode in the aprotic polar solvent of dimethyl sulfoxide (DMSO) has been systematically investigated by electrochemistry in combination with *in-situ* UV-Vis absorption spectroscopy, surface-enhanced Raman vibrational spectroscopy (SERS) and *ex-situ* infrared spectroscopy [5].

In the Li-free DMSO solution, O<sub>2</sub> is efficiently reduced to the superoxide, which forms an ion-pair with the tetrabutylammonium (TBA) cation and shows an excellent stability in DMSO. The adsorption of the superoxide on the gold electrode surface has been observed by an *in-situ* SERS measurement. When the Li-ion is included in the DMSO, O<sub>2</sub> can be further electrochemically reduced to lithium peroxide (Li<sub>2</sub>O<sub>2</sub>) and deposited on the electrode surface. Figure 1 shows *in-situ* SERS measurement for the ORR/OER processes in O<sub>2</sub>-saturated 0.1M LiClO<sub>4</sub>-DMSO solution. In addition to the peaks from solvent and supporting electrolyte, a Raman peak was clearly observed 788 cm<sup>-1</sup> with the ORR current. This Raman band can be attributed to O-O stretching mode of Li<sub>2</sub>O<sub>2</sub> on the Au surface, indicating that Li<sub>2</sub>O<sub>2</sub> is formed on the electrode surface. Detailed analyses on the potential dependence of the Raman peak intensity, it was found that the Li<sub>2</sub>O<sub>2</sub> formation is a kinetically-controlled process and terminated at a certain film thickness on the electrode surface. At the same time, a large amount of superoxide is still produced in the solution which shows a UV-Vis absorption spectrum similar to that polarized in the Li-free DMSO solution, implying that Li-ions solvated by DMSO make ion-pairs with superoxide (denoted as LiO<sub>2</sub>) in solution. On the other hand, no evidence for the disproportionation reaction of LiO<sub>2</sub> to Li<sub>2</sub>O<sub>2</sub>, one of known reaction mechanisms proposed before [2], has been obtained in the bulk solution and on the electrode surface in the present study.

Fig. 1 *in-situ* Raman spectra on sputter gold surface in O<sub>2</sub> saturated Li-DMSO electrolyte.

Based on the quantitative analyses of the *in-situ* spectroscopic observations, the partial yields for LiO<sub>2</sub> and Li<sub>2</sub>O<sub>2</sub> have been estimated to elucidate the mechanism for the ORR/OER processes [5]. The present results are discussed in comparison to previous observations on porous carbon cathodes regarding the surface area, morphology as well as three-phase interface on the electrode and solution interface.

Detailed results and discussion will be given in the presentation.

kmotobayashi@cat.hokudai.ac.jp

Room temperature ionic liquids (RTILs) are promising electrolyte materials owing to their fascinating properties such as high thermal and electrochemical stabilities. However, the structure and dynamics of RTILs at the vicinity of electrodes are still under debate. Recently we reported hysteretic potential-dependence of ion density and orientation of [BMIM][TFSA] (Fig.), one of the RTILs with relatively high diffusivity and conductivity, on an Au electrode.<sup>1</sup> Spectroscopic studies of RTIL/electrode interfaces including ours have been performed with pure ionic liquids in vacuum or dry atmosphere to eliminate the effect of dissolved impurities. To understand what happens at the real interfaces such as those in batteries and capacitors, it is necessary to study potential-dependent behaviour of RTILs with additives such as water and Li<sup>+</sup> ions. Surface enhanced infrared absorption spectroscopy (SEIRAS) that can selectively probe solid/liquid interfaces is suited for this purpose. In the present work, we investigated how the additives affect the potential-dependent behaviour of [BMIM][TFSA] at the vicinity of an Au electrode by SEIRAS.

SEIRAS experiments have been performed on an Au thin film electrode chemically deposited on a Si prism in a vacuum-compatible glass cell. The electrode potential was controlled by a potentiostat against a Pt quasi-reference electrode and corrected by the redox potential of Fc/Fc<sup>+</sup> couple. Concentrations of water and Li<sup>+</sup> ion in RTILs were controlled by exposure to water-saturated Ar gas and addition of Li[TFSA], respectively.

Potential-dependent SEIRA spectra of [BMIM][TFSA]/Au electrode showed the threshold potentials for steep increasing/decreasing in the intensities of the vibrational bands, which indicated the existence of the energy barrier for anion-cation exchange at the first ionic layer on the electrode [1]. Addition of water to [BMIM][TFSA] did not affect the threshold potential for the anion-cation exchange, but resulted in higher slope of the increase in band intensities as a function of the potential. This indicates that the energy barrier for ion exchange at the first ionic layer remains even in the presence of water but the ion exchange becomes faster due to reduced Coulombic interaction between ions. On the other hand, addition of the Li salt results in more positive threshold potential for the exchange of cations to anions at the first layer. We concluded that the anionic complex (probably [Li(TFSA)<sub>2</sub>]<sup>-</sup>) have higher potential barrier to replace cations at the first layer than TFSA<sup>-</sup> owing to its bulky structure. The formation of anionic Li complex is supported by the decrease of the band intensity of the solvated TFSA<sup>-</sup> at potentials negative of pztc (potential of zero total charge). Anionic Li complex moves further away from the electrode at the negative potential. The different environment of water and Li ion in the vicinity of the electrode surface relative to that in the bulk liquid will be also reported in the presentation.

# An Infrared Study of the Few-Layer Graphene | Ionic Liquid Interface: Correlation between Electronic and Ionic Surface Structure

Ove Oll, Tavo Romann, Enn Lust  
Institute of Chemistry, University of Tartu  
Ravila 14a, Tartu, 50411 Estonia  
ove.oll@ut.ee

Detailed understanding of the interface between graphitic carbon materials and concentrated electrolytes is of great importance for the rational design of novel high energy and power density supercapacitors. It is of particular interest to describe how the limitation of quantum capacitance of semimetal electrodes influences the electrolyte part of the electrical double layer (EDL).

A novel technique of *in situ* infrared absorption (IRA) spectroscopy for the study of few-layer graphene (FLG) electrodes has been developed[1] and is applied for the study of the FLG|1-ethyl-3-methylimidazolium tetrafluoroborate (EMImBF<sub>4</sub>) ionic liquid interface. The surface specificity of the technique, as well as the plasmonic enhancement properties of the electrode is demonstrated. The IRA results show that, unlike previous theoretical considerations of the EDL between semimetals and electrolytes, the strong interaction between the electronic and ionic part of the EDL is of fundamental importance for the description of semimetal interfaces. Together with the data provided by *in situ* electroreflectance[1] technique of the electronic and energetic structure of the FLG electrode and differential capacitance potential dependence of the FLG|EMImBF<sub>4</sub> system, it is demonstrated that the screening of excess surface charge by the ionic liquid is strongly correlated with the potential dependent electronic properties of the electrode. This result is in agreement with our previous studies of semimetal interfaces, such as porous carbon[2] and thin-layer bismuth electrodes[3] in ionic liquid electrolyte.

# Influence of Electrolyte on Sulfur Redox Reactions: Combined RRDE and *in situ* UV-VIS Studies

Qingli Zou and Yi-Chun Lu\*

Department of Mechanical and Automation Engineering, The Chinese University of Hong Kong  
Shatin, N.T., Hong Kong SAR, China

\*yichunlu@mae.cuhk.edu.hk

Fundamental understanding of lithium–sulfur(Li-S) redox reactions is critical for realizing efficient and long-lasting rechargeable Li-S batteries.<sup>1-2</sup> Recently, we exploited rotating ring-disk electrode (RRDE) technique and specially-designed Li-S catholyte cell to examine sulfur reduction and oxidation behaviors in 1,3-dioxolane:1,2-dimethoxyethane (DOL:DME) and dimethyl sulfoxide (DMSO).<sup>3</sup> We showed that only part of the sulfur reduction capacity is obtained through direct electrochemical steps, and that the rest of the capacity is achieved via various subsequent chain-growth and disproportionation reactions that generate reducible species.<sup>3</sup> In addition, the reaction rates of electrochemical and chemical reactions of sulfur redox reactions directly influence the performance of metal sulfur batteries.<sup>3</sup>

In this study, we investigate the influence of both solvent and salt on the metal–S redox and disproportionation behaviors combining RRDE and *in situ* UV-Vis spectroscopic techniques. Figure 1 shows the *in situ* UV-VIS spectra of elemental sulfur ( $S_8$ ) reduction in lithium-containing salt in DMSO (blue series) and DOL:DME (red series) during *in situ* scan of cyclic voltammetry on a gold electrode. Reported reference UV-VIS spectra for various polysulfides are labeled.<sup>4,5</sup> Generally, longer polysulfide shows absorption at longer wavelength where shorter polysulfide shows absorption at shorter wavelength (except the  $S_3^{\cdot-}$  radical).<sup>4,5</sup> Upon reduction in DMSO (from dark blue to light blue),  $S_8^{2-}$  firstly formed as the predominant reduction product, which then dissociate to the  $S_3^{\cdot-}$  radical or further reduced to low-chain polysulfide between  $S_3^{2-} / S_4^{2-}$  and  $S_3^{2-} / S_2^{2-}$ . This is consistent with various reported studies<sup>6</sup> in high-dielectric solvents such as DMSO ( $\epsilon_{\text{DMSO}} = 46.5$ ).<sup>7</sup> Interestingly, neither high-chain polysulfides nor  $S_3^{\cdot-}$  radical can be identified during the *in situ* CV scanning in DOL:DME. This suggests that the long-chain polysulfides ( $S_8^{2-}$  and  $S_6^{2-}$ ) and the  $S_3^{\cdot-}$  radical are not stable in low-dielectric solvent ( $\epsilon_{\text{DOL}} = 7.13$ ;  $\epsilon_{\text{DME}} = 7.075$ )<sup>7</sup> and quickly disproportionate to shorter chain such as  $S_4^{2-}$ ,  $S_3^{2-}$  and  $S_2^{2-}$ . This result shows that such chemical disproportionation process is relative fast since the *in situ* UV-VIS scan cannot detect the appearance of long-chain polysulfides even with sub-second interval of UV-VIS collection. This is consistent with our hypothesis that the rates of the chemical chain-growth/disproportionation reactions are higher in low-dielectric solvents such as DOL:DME compared to high-dielectric solvents such as DMSO due to its poor stabilization of polysulfides. In-house reference samples of various polysulfide species in both DMSO and DOL:DME will be examined under the same UV-VIS configuration for accurate comparison. Detailed UV-VIS and RRDE investigation on the influence of both solvent and salt on the electrochemical and chemical processes of S-reduction and oxidation reactions will be discussed. **References:** (1) Bruce et al. *Nat. Surface enhanced Raman scattering (SERS) has been usually conducted at rough surfaces of coinage metals because the nanometric surface features are needed for plasmonic enhancement of Raman signal intensity. Recently, we have reported on SERS observations on single crystalline Au surfaces of various orientations using sphere-plane type nanogap structures.<sup>1-4</sup> This technique has been also applied for observing well-defined surfaces of weak-SERS-active metals such as platinum group metals (PGMs).<sup>5-7</sup> The SERS study on atomically defined and ideally uniform surfaces indeed improve our understanding of metal-molecule interactions. However, it is also known that atomic local surface sites often exhibit unique activity in the fields of heterocatalysis or electrocatalysis. Therefore, selective observation of atomic local sites is needed for deeper understanding of metal-molecule interactions.

In the present work, we fabricated atomic Pd islands on defect sites of Au(111) such as step lines using the underpotential deposition technique. We then observed SERS spectra of molecular adsorbates on the Pd islands selectively by forming SERS active nanogap structures only on Pd atomic sites. When the Pd coverage was at the order of a few percent, the observed spectra varied with increasing the two-dimensional size of Pd islands, suggesting that the adsorption geometry of the molecules was sensitive to the local surface structures on the atomic scale.

# Theoretical Simulation of Solid Electrolyte Interphases

Sara Panahian Jand, Payam Kaghazchi

*Physikalische und Theoretische Chemie, Freie Universität Berlin*

*Takustr. 3, 14195 Berlin, Germany*

*sara.jand@fu-berlin.de*

The solid electrolyte interphase (SEI) is a heterogeneous layer that is formed on the surface of electrodes in Li-ion batteries during the first charging cycles (due to the reduction of electrolyte species). The SEI layer plays a key role in the stability and operating parameters of Li-ion batteries. Therefore, a fundamental understanding of the structure of SEI layer is a prerequisite to develop high-performance Li-ion batteries.

In this work, we will present our theoretical studies on the structure of SEI layers. We will first discuss our density functional theory (DFT) calculations for LiF and Li<sub>2</sub>O nanoclusters on graphene, which have been observed in a recent experimental study [1]. We will show that, independent of being in contact or not with a graphene surface, crystalline-LiF nanoclusters with {100} facets grow in a three dimensional mode, but Li<sub>2</sub>O nanoclusters are amorphous [2]. These results are in agreement with the TEM images [1]. Furthermore, we will introduce a method to construct transferable force fields (FF) for inorganic components of the SEI layer (e.g. LiF and Li<sub>2</sub>O). The FF parameters are obtained by comparing physical quantities calculated with DFT and those calculated with classical potentials. We will show that the constructed FF gives similar atomic structures and stabilities (for nanoclusters and surfaces) to those obtained using DFT calculations [3].

Finally, we will present our recently developed quantum mechanics/molecular mechanics (QM/MM) approach, which can be used to study the electronic structure and ionic conductivity in the interfaces of SEI components [3].

*Krischer@tum.de*

The electrochemical oxidation of CO on platinum electrodes exhibits a variety of nonlinear phenomena, such as bistability in the current-potential curve and current oscillations under potentiostatic conditions, or the formation of stable spatial domains with different CO coverages, and thus different reactivities, under galvanostatic conditions. In the talk, I will discuss recent results on self-organized reactivity patterns which form during the oxidation of CO in the presence of an electrolyte flow parallel to the electrode. Patterns in the CO coverage are recorded by means of spatially resolved ATR-FTIR spectroscopy. Typical patterns observed are tongue-shaped structures that align parallel to the flow and move in the direction perpendicular to the flow (Fig. 1). These wave fragments possess several peculiar properties: They may split, sending out a second wave in the backward direction; Two colliding waves penetrate each other forming a soliton-type collision state; Open ends do not grow into a spiral wave but propagate with a stable shape. Basic features of the dynamics can be understood on the basis of a model taking into account the reaction kinetics of CO oxidation, diffusion of CO parallel to the electrode and advection of CO, i.e. the transport of CO by the flow. Especially, the role of advection for pattern formation will be elaborated.

# Designing Better Electrocatalysts by Simply Counting Surface nearest Neighbors

federico.calle-vallejo@ens-lyon.fr*

The surface of a heterogeneous catalyst is normally composed of a variety of terraces and defects. Close-packed surfaces coexist with more open facets, steps and kinks. Among all those, it is often observed that only one specific type of sites is catalytically active, which gives rise to the concept of structure sensitivity [1, 2]. In order to achieve maximal catalytic activities, materials design techniques should identify those sites and suitable synthesis procedures must be used to increase their surface abundance.

Well-known computational methodologies such as Sabatier-type activity plots are able to determine the adsorption features of optimal electrocatalysts [3]. However, countless materials can possess such adsorption features, so additional material screenings are performed over large databases created from DFT calculations [4], which is rather time consuming. Therefore, more descriptive guidelines are needed to enable the rapid design of new catalysts and avoid exhaustive computational and experimental searches.

In this talk we will present a methodology to predict not only the adsorption features of optimal catalysts but also the geometric structure of their active sites. The methodology can take into account all types of sites on nanoparticles of different sizes [5]. We will illustrate the method on the particular case of the electrochemical oxygen reduction reaction catalyzed by platinum, where our technique provides a morphology rationale used to engineer highly active sites, without resorting to alloying and using three different affordable experimental methods.

[i.katsounaros@umail.leidenuniv.nl](mailto:i.katsounaros@umail.leidenuniv.nl)

Ammonia is an essential component of the nitrogen cycle, as it is involved in a variety of natural or industrial processes of paramount importance, such as the biological nitrification in soil or the ammonia synthesis (nitrogen fixation). The oxidation of ammonia by electrochemical means may find applications in (i) energy conversion (ammonia fuel cells or “ammonia electrolysis”), (ii) ammonia sensors, (iii) environmental protection (removal of ammonia from waste streams), or (iv) electrosynthesis (e.g. production of hydroxylamine or nitric acid).

Nitrogen gas is the most favorable product of ammonia oxidation in terms of thermodynamics; however, its selective formation is in fact difficult. Platinum is the most active for the electrochemical oxidation of ammonia to nitrogen compared to other noble and transition metal polycrystalline surfaces. According to the two early mechanisms that have been proposed to describe the conversion of  $\text{NH}_3$  to  $\text{N}_2$ , nitrogen can be formed either by the  $\text{N}_{\text{ad}}$  dimerization or by recombination of two  $\text{NH}_x$  adsorbed species ( $x = 1, 2$ ). From experimental and computational studies there is not yet a consensus on the dominant mechanism of nitrogen formation during ammonia oxidation.

The activity of platinum for the conversion of ammonia to nitrogen relies on the presence of Pt(100) terraces, which are unique for this reaction. In particular, ammonia oxidation is a very structure-sensitive process, as Pt(100) is the only one of the three Pt basal planes which can convert  $\text{NH}_3$  to  $\text{N}_2$  selectively, while Pt(111) and (110) are practically inactive.

This presentation deals with the ammonia oxidation on the Pt(100) single-crystal electrode in alkaline solutions, using standard electrochemical methods in combination with electrochemical fourier transform infrared reflectance-absorption spectroscopy and differential electrochemical mass spectrometry. Our particular focus is on the nature of the adsorbed intermediate species and thereby on their potential role in the N-N coupling and the observed deactivation.

# Oxygen Electroreduction at Non-uniform Pt Surfaces: From Model Electrodes to Nanostructured Catalysts

Aliaksandr Bandarenka

*Technische Universität München*

*Department of Physics, James-Frank-Str. 1, D-85748 Garching, Germany*

*bandarenka@ph.tum.de*

Electrocatalysis of the oxygen reduction reaction (ORR) is significant for both fundamental and applied electrochemistry, as it can be the key reaction for the future sustainable provision of renewable energy. Additionally, the ORR has become an important model process, which is critical for the better understanding of reactions at electrified solid / liquid interfaces.

It is now relatively well understood that an ideal catalyst for the ORR should bind the OH-reaction intermediates approximately 0.1 eV weaker than the model Pt(111) surface [1]. However, application of this knowledge to design “real-world”, often nanostructured electrocatalysts is not always straightforward. For instance, surface defects should normally bind the reaction intermediates stronger; therefore, defect surfaces are expected to have lower activity than Pt(111). This is indeed the case for the polycrystalline platinum electrodes. However, introduction of specific surface defects, for instance steps, can also substantially increase the catalytic activity. This is typical for e.g. Pt[n(111)x(111)] and Pt[n(111)x(100)] surfaces [2,3,4]. On the other hand, “normal-shape” Pt nanoparticles, which have large amount of under-coordinated sites (similar to those present at the high-index single crystal surfaces), do not demonstrate such non-trivial increase in the activity. Another surprising phenomenon is the dependence of the ORR specific activity of nanoparticles on both loading [5] and long-range order [6].

While the common way of improving the activity of metal electrodes is a modification of the electronic properties of the surface through alloying it with other metals, it turned out that in case of bulk alloys, the solute metal often dissolves from the surface layers. This leads to structures in which several strained Pt-enriched layers cover the bulk alloy and protect it from further dissolution. Namely strains in the resulting layers influence the ORR activity [1,7]. However, these systems are difficult to model, as the resulting structures are complex and highly dependent on preparation methods.

In the presentation, examples will be given of how to explain or even predict the non-trivial activity phenomena for high-index single crystal surfaces, polycrystalline electrodes and nanostructured materials using affordable experimental and theoretical approaches.

The oxygen reduction reaction (ORR) is probably the most studied electrochemical reaction because its practical application on fuel cells and batteries. It has been mainly studied on aqueous solution but in recent years the research on of metal-air batteries using non-aqueous solvents has triggered the studies on those solvents. When water is replaced by other solvents, the interactions between the solvent and the electrode surface alter the reactivity of the electrode. These interactions of the solvent with the surface have to be perfectly understood if better electrocatalysts are to be designed. In order to study those effects, the ORR has been studied on platinum single crystal electrodes in hanging meniscus rotating disk configuration using aqueous solutions with different concentrations of acetonitrile. Acetonitrile, a small organic molecule, can be used as a paradigm of the possible interactions that can be found in a non-aqueous solution. For understanding the differences with water, low and high concentrations of acetonitrile have been used. On Pt(111) electrode, increasing amounts on acetonitrile leads to a higher onset for the ORR and lower limiting currents, a clear indication that the adsorption of acetonitrile is giving rise to the formation of some hydrogen peroxide as final product. For high acetonitrile concentrations, the limiting current is half of that obtained in the absence of acetonitrile, and thus the efficiency for hydrogen peroxide formation is approaching 100%. The half wave potential for the reaction almost coincide with the thermodynamic potential for the reduction of oxygen to hydrogen peroxide (=0.68 V) and thus suggesting that this reaction is taking place with a very low overpotential. For the Pt(100), lower currents and higher overpotentials are always obtained.

To understand those differences with the surface structure, the FTIR spectra of the process in deaerated solutions has been recorded. For the Pt(111) electrode, adsorbed acetonitrile is observed at high potentials, as previously reported [1]. Around 0.6 V, a reductive process in the adsorbed acetonitrile species takes place, which leads to changes in the adsorbed configuration. On Pt(100) electrode, this process takes place at much higher potentials. DFT calculations indicate that the presence of this reduced species is a key parameter in the formation of hydrogen peroxide. It can effectively transfer hydrogen atoms to adsorbed O-O species on Pt, leading to the formation of hydrogen peroxide.

## [Introduction]

A well-organized molecular monolayer can be self-assembly constructed on a metal surface. Such chemical modification is recognized as one of key issues to functionalize metal electrode surfaces. For example, metalloporphyrin-modified electrodes are known to act as electrocatalysts for oxygen reduction reaction (ORR). However, the reaction rate on such electrodes is significantly affected by electronic coupling between the metal substrate and catalyst molecules. In this work, we constructed Cobalt porphyrin(CoTPP)-modified electrodes with various metal-molecule interface structures using the layer-by-layer technique. The contribution of the interface structures to the overall reaction rate was examined by analyzing the polarization curves of ORR.

## [Experimental]

CoTPP-catalyst layers were immobilized on an Au electrode through various molecular wires such as alkanethiols or phenyldiisocyanides. To tune the interface structure between the wire molecules and the metal substrate, Pd monoatomic layers (Pd<sub>ML</sub>) were formed by the underpotential deposition technique. ORR was measured using the rotating disk electrode (RDE) method in oxygen-saturated 0.5 M H<sub>2</sub>SO<sub>4</sub> electrolyte solution.

## [Results and Discussion]

The upper panel of the figure illustrates the interface structures between the electrode and wire molecules with and without Pd<sub>ML</sub>. The adsorption geometry of the isocyanide anchor group (-CN) was confirmed using the infrared reflection absorption spectroscopy. In the presence of Pd<sub>ML</sub>, the anchor geometry changed from the on-top to the bridge configuration, indicating the stronger adsorption on Pd than on Au. In the case of thiols (-S), on the other hand, the presence of Pd<sub>ML</sub> is expected to weaken the adsorption.

The lower panel of the figure shows the polarization curves for ORR on the CoTPP-modified electrodes with the four different interface structures: Au-S, Au/Pd<sub>ML</sub>-S, Au-CN, and Au/Pd<sub>ML</sub>-CN. The difference of the ORR overpotential between Au-S and Au-CN was rather small. In the presence of Pd<sub>ML</sub>, however, the two anchor groups exhibited opposite tendency; Au/Pd<sub>ML</sub>-S showed larger ORR overpotential whereas Au/Pd<sub>ML</sub>-CN presented much smaller overpotential. This result clearly shows that the overall electrochemical reaction rate is strongly affected by the interface connection between the catalytic active sites and the conducting electrode even in rather slow ORR.

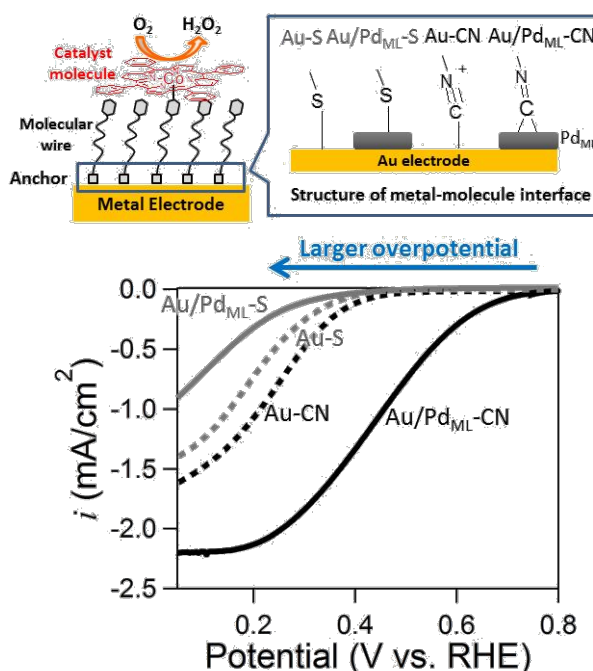

Figure. ORR polarization curves on Co-TPP catalyst layers formed on the molecular wire monolayer of Imidazole-terminated alkanethiols and isocyanides with and without Pd<sub>ML</sub>, measured by RDE method with rotation rate of 1000 rpm.

This result clearly shows that the overall electrochemical reaction rate is strongly affected by the interface connection between the catalytic active sites and the conducting electrode even in rather slow ORR.

# Designing In Situ Solid Electrolyte Interphase Studies using Surface-enhanced Raman Spectroscopy

Sunny Hy<sup>a,b</sup>, Felix<sup>b</sup>, Bing-Joe Hwang<sup>b</sup>

<sup>a</sup>Department of NanoEngineering, University of California San Diego, La Jolla CA USA

<sup>b</sup>Department of Chemical Engineering, National Taiwan University of Science and Technology, Taipei Taiwan  
SIhy@ucsd.edu

The mechanical and chemical properties of the solid electrolyte interphase (SEI) on the electrode surface dictates the overall battery properties that include rate performance, capacity retention and durability. Although extensive work has been done to try and elucidate its growth mechanism, transport properties, and chemical make-up, it still remains highly elusive due to its nano-scale thickness and complex heterogeneous structure<sup>1</sup>. To understand its chemical evolution during cycling, we developed an in situ surface-enhanced Raman Spectroscopy technique utilizing nano-sized Au particles coated with a chemically-inert SiO<sub>2</sub> coating that is applied directly to the electrode being studied. The use of the nano-sized Au particles allows for the exploration of different electrode systems that often determine the chemistry and growth mechanism of SEI. Here we demonstrate the feasibility of the technique looking at silicon electrode with two different electrolytes<sup>2</sup>, its use to elucidate the reaction mechanisms occurring on both cathode and anode surface within a lithium-excess cathode and graphite cell configuration<sup>3</sup>, and finally possible strategies for improving this novel technique such as applying Ag nanoparticles to explore surface ALD-coated cathode materials during in situ cycling.

Figure 1 in situ SERS spectra during charging up to 4.8 V of the Al<sub>2</sub>O<sub>3</sub> ALD coated Li-excess cathode material

*juan.feliu@ua.es*

Room temperature ionic liquids are a novel kind of solvents potentially suitable for many electrochemical applications. A deeper knowledge of the properties that characterize the metal /ionic liquid interphase is desirable for understanding its reactivity. However, in the case of platinum group metals, the number of available studies is very limited, especially on single crystal electrodes [1, 2]. The high electrocatalytic activity of platinum complicates the study of its interfacial properties. One of the main difficulties lies on the determination of the potential of zero charge, pzc, a very important interfacial parameter, whose calculation is not straightforward, even in aqueous solution.

Laser-induced temperature jump experiments provide information on the entropy changes of the double layer from which the potential of maximum entropy, pme, is available. The experimental response is dominated by the organization of the ionic network at the interface and is closely related to the pzc. From an electrostatic point of view, at potential values more negative than the pzc, the ionic network at the interphase should contain higher number of cations than anions and the response obtained from the laser perturbation should be negative. This response should decrease in magnitude by increasing the applied potential, as a consequence of the composition change. If the amount of cations equals that of anions, the response would be zero. In the absence of specific interactions, the pme should approach the pzc. The same, but opposite trends, should take place at potentials positive to the pzc.

The interface Pt(111)/[Emmim][NT2f] is investigated by laser-induced temperature method [3]. Comparison with similar analysis in aqueous solution, in a very wide pH range, show the differences between this novel interface and classical Pt/aqueous interfaces. Although the experimental response is potential dependent, thus revealing the different distribution of ions in the network as a function of the applied potential, the interchange between cation and anion is not as simple and depends on many parameters. All these considerations will be discussed.

# C1 Molecule Adsorption-Dissociation on Pt and Cu-modified Pt Electrode Surfaces

Kun Jiang,<sup>1,2</sup> Sylvain Brimaud,<sup>2</sup> Wen-Bin Cai<sup>1</sup> and R. Jürgen Behm<sup>2</sup>

<sup>1</sup> Collaborative Innovation Center of Chemistry for Energy Materials and Department of Chemistry, Fudan University, Shanghai 200433, P.R. China

<sup>2</sup> Institute of Surface Chemistry and Catalysis, Ulm University, D-89069 Ulm, Germany  
e-mail: [wbc@fudan.edu.cn](mailto:wbc@fudan.edu.cn); [juergen.behm@uni-ulm.de](mailto:juergen.behm@uni-ulm.de)

The adsorption and oxidation behavior of C1 organic molecules like CH<sub>3</sub>OH, HCHO and HCOOH is of general importance not only from fundamental reasons, as model reactions in electrochemistry, but also because of their potential applications as fuel for green power sources like direct alcohol fuel cells. However, compared with the hydrogen oxidation reaction, the reaction mechanisms and intermediates formed during their reactive dissociation and oxidation on platinum group metal surfaces are far more complicated with several potential-dependent adsorbed intermediates [1].

Here we report results of a comparative investigation on the adsorption and dissociation behavior of methanol, formaldehyde and formic acid on Pt and Cu-modified Pt surfaces, employing a flow cell setup combined with *in situ* Attenuated Total Reflection Fourier Transform Infrared Spectroscopy (ATR-FTIRS) and online Differential Electrochemical Mass Spectrometry (DEMS), which allows for the simultaneous detection of adsorbed species and volatile products [2]. Negligible DEMS signals for volatile CO<sub>2</sub>, CO or HCOOCH<sub>3</sub> were recorded at fixed potential within the H<sub>upd</sub> region on both electrodes upon C1-molecules adsorption. However, differences were observed for the partially dissociated intermediates and for the CO<sub>ad</sub> coverages for Pt surface and the Pt surface modified by Cu-adlayer. Further measurements employing deuterated C1 compounds were also carried out for a better identification of the adsorbed intermediates. The overall implications of these findings on the reactive adsorption and dissociation processes will be discussed in this presentation.

**Figure 1.** Time-resolved band intensity for intermediates during CH<sub>3</sub>OH adsorption-dissociation on either Pt or a Cu-modified Pt surface as monitored by *in situ* electrochemical ATR-IR

# Direct observation of electrochemical processes at single atomic layer: an advanced optical microscopy study

M.Azhagurajan<sup>1</sup>, Takashi Itoh<sup>1</sup>, and K. Itaya<sup>1</sup>.

<sup>1</sup>Frontier Institute for Interdisciplinary Sciences, Tohoku University, 6-3 Aramaki Aoba, Sendai  
980-8578, JAPAN

The evaluation of dynamic processes of electrochemical reactions of metals is an extremely important subject for both fundamental and practical points of view.[1,2] Although in situ SPM techniques can reveal those processes with atomic levels, observable scan areas are usually small electrochemical reactions taking place in the entire area of electrode surface. However due to slow scan speed and small observation area (usually in nanometer scale), the overall electrochemical process has not been understood completely.

In this study, we employed an optical microscopy technique called laser confocal microscopy-differential interference contrast microscopy (LCM-DIM) to understand the electrochemical dissolution/deposition process. The LCM-DIM has many capabilities of resolving mono-molecular steps and single atomic steps on Au, Pt, Pd and Si single crystal surfaces. We have also succeeded to see mono-molecular steps on many organic single crystal surfaces. The monatomic steps with a height of 0.23 nm on ultra-flat Pd (111) and 0.25 nm on ultra-flat Au (111) were clearly discerned in electrolyte solutions by this advanced optical microscopy, LCM-DIM. Figure 1(A) shows a LCM-DIM image obtained on the entire area of an ultra-flat Au (111) facet formed on a small single crystal bead [3].

Large (111) facets are usually formed on a relatively large crystal. Figure 1(B) shows an illustration of the deposition of Au in the atomic scale. Direct observation of electrochemical deposition and dissolution process at single atomic layer on ultra-flat Au (111) was shown in this study. It is indicated that the electrochemical processes of Au (111) can be followed with atomic step resolution. Detailed results will be discussed. Thus, it is evident that the combination of electrochemistry along with LCM-DIM is a potential technique for observing interfacial phenomena which can then be applied directly for an industrial scale application.

# Enhanced Electrocatalysis of Ethanol on Dealloyed Pd-Ni-P Film in Alkaline Media: an Infrared Spectroelectrochemical Investigation

Ye Wang, Wen-Bin Cai\*

Collaborative Innovation Center of Chemistry for Energy Materials and Department of Chemistry,  
Fudan University, Shanghai 200433, China  
wbcai@fudan.edu.cn

Dealloying treatment is an effective way to restructure bi- and tri- metallic catalytic materials, with an expectation to enhance a desired electrocatalytic reaction<sup>[1]</sup>. In order to further extend the application of dealloyed catalysts in electrocatalytic applications, fundamental understanding of the interfacial reactions occurring at corresponding electrode/electrolyte is essential. As a case study, electrocatalysis of ethanol in alkaline media on dealloyed Pd-Ni-P film has been recently investigated in our group<sup>[2,3]</sup>. A Pd-Ni-P film was electro-deposited on Au substrate, and the dealloying process was carried out by repetitive potential cycling in acidic media to leach out most Ni and P components. Surface structural and electronic properties of the pristine film and the dealloyed film were characterized and compared. Surface roughening, Pd-segregation and electronic property variation upon dealloying were confirmed. Cyclic voltammetry and chronoamperometry on the two films in ethanol-containing alkaline media were used to assess their electrocatalytic performances, demonstrating significantly enhanced and durable ethanol oxidation on the dealloyed film. More importantly, in situ attenuated total reflection surface enhanced infrared spectroscopy was initially extended to probe the interfacial molecular variations associated with the electrocatalytic reactions on these two films, to provide an insight into the enhanced electrocatalysis on the dealloyed film. It was revealed that the enhanced electrocatalysis correlates well with enhanced formation of both CO<sub>ad</sub> and acetate.

**Figure 1.** Potentiodynamic ATR-SEIRA spectra on the as-deposited Pd-Ni-P film (A) and the dealloyed film (C) in 0.1 M NaOH + 0.5 M CH<sub>3</sub>CH<sub>2</sub>OH; Potential-dependent band intensities for  $\nu(\text{CO}_{\text{ad}})$  (blue) and  $\nu_{\text{s}}(\text{OCO})$  of adsorbed acetate (green) with corresponding cyclic voltammograms recorded at 5 mV s<sup>-1</sup> on the as-deposited Pd-Ni-P film (B) and the dealloyed film (D) in 0.1 M NaOH + 0.5 M CH<sub>3</sub>CH<sub>2</sub>OH. Reference spectrum was taken at OCP in 0.1 M NaOH.

**Acknowledgements:** Financial supports from NSFC (grant No. 21273046 and 21473039) and SMCS (grant No.11JC140200) are highly appreciated.

# Raman Spectroscopic Detection of Electrochemical Oxidative Reaction of Single-Walled Carbon Nanotubes

Masato Tominaga,<sup>\*†‡</sup> Yudai Nagahama,<sup>†</sup> and Yuto Yatsugi<sup>†</sup>

<sup>†</sup>Graduate School of Science and Technology, Kumamoto University, Kumamoto 860-8555, Japan

<sup>‡</sup>Kumamoto Institute for Photo-Electro Organics (Phoenix), Kumamoto 862-0901, Japan

<sup>\*</sup>masato@gpo.kumamoto-u.ac.jp

The oxidative corrosion of carbon is an urgent problem because carbon is widely used as a platform electrode to immobilize catalysts. One of the factors in the gradual decrease of output power in fuel cells such as a polymer electrolyte fuel cell is the oxidative corrosion of the carbon supports. The oxidative corrosion of carbon is a complicated process that includes parallel oxidation pathways. Furthermore, the following electrochemical oxidation reaction ( $\text{C} + 2\text{H}_2\text{O} = \text{CO}_2 + 4\text{H}^+ + 4\text{e}^-$  0.207 V vs. NHE) of carbon by water molecules occurs at a much more negative potential than that thermodynamically expected, although the rate of this reaction is very slow. Understanding the mechanism of nucleation and growth in oxidative corrosion at the surface of  $\text{sp}^2$ -carbon is important for advancing its application. A considerable amount of electrochemical research has been directed towards elucidating the mechanism of the oxidation of the hexagonal plane  $\text{sp}^2$  carbon family, such as highly oriented pyrolytic graphite (HOPG), carbon nanotubes and graphene as model reaction systems. Recently, a number of studies using *ab initio* molecular orbital calculations have focused on the oxidation steps of hexagonal plane  $\text{sp}^2$  carbons. However, the detailed oxidation mechanism of such  $\text{sp}^2$  carbons is still unclear.

We recently reported the oxidative corrosion potential vs. pH diagram for single-walled carbon nanotubes (SWCNTs), as shown in Figure 1.<sup>1,2</sup> The Raman spectroscopy studies based on the encapsulation of  $\beta$ -carotene into SWCNTs revealed that there are three types of oxidative corrosion of SWCNTs: non-oxidized, end-cap oxidized (end-cap eliminated), and side-wall oxidized SWCNTs. SWCNTs are good models for experimentally analyzing the oxidative corrosion of  $\text{sp}^2$ -carbon. Furthermore, the effect of adsorbed molecular oxygen on the oxidative corrosion of SWCNTs in aqueous solution has been investigated using Raman spectroscopy.<sup>2</sup> We found that nucleation and growth of the oxidative corrosion began at defect sites in the presence of adsorbed oxygen, but occurred randomly in the absence of adsorbed oxygen. Similar behavior was observed for metallic-type SWCNTs (m-SWCNTs) and semiconductor-type SWCNTs (s-SWCNTs).

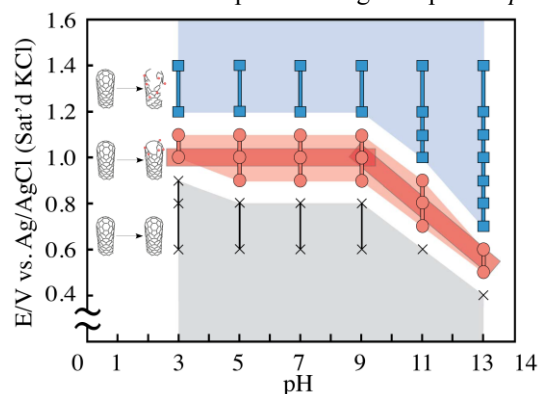

Figure 1. Diagram of potential vs. pH for the oxidative corrosion of SWCNTs (crosses: non-oxidized SWCNTs, circles: end-cap eliminated SWCNTs, squares: sidewall and end-cap oxidized SWCNTs).

# Electrochemistry of Two-Dimensional Materials

Matěj Velický<sup>a,\*</sup>, P.S. Toth<sup>a</sup>, M.A. Bissett<sup>a</sup>, I.A. Kinloch<sup>b</sup>, K.S. Novoselov<sup>c</sup>, Robert A.W. Dryfe<sup>a</sup>

<sup>a</sup>School of Chemistry, <sup>b</sup>School of Materials, <sup>c</sup>School of Physics and Astronomy, University of Manchester, Oxford Rd, Manchester, M13 9PL, UK

\*matej.velicky@manchester.ac.uk

Two-dimensional (2D) materials have generated enormous interest in electrochemistry-related applications, such as sensing and energy storage/conversion or corrosion protection [1]. Electrochemical performance of these materials is critical for their successful implementation in the abovementioned applications. Despite significant advances in the last five years, the electrochemistry of graphene remains far from being fully understood and there is currently a lack of consensus on some of its basic electrochemical properties. Furthermore, the recent surge in exploration of other 2D materials, such as MoS<sub>2</sub>, WSe<sub>2</sub> or h-BN, which have been studied far less than graphene, has opened a much wider landscape of possibilities in optoelectronics, electrochemical switching and photocatalysis, due to their complex electronic structure.

We address the key aspects of 2D materials' electrochemistry using a unique electrochemical probe, capable of measuring electrochemical response on a micrometer scale, and a range of microscopic and spectroscopic techniques. The key properties discussed here are: *charge transfer kinetics*, *capacitance*, and their dependence on the number of graphene layers and the role of defects/edges. Contrary to previous views, the basal plane of graphene is electrochemically active and there is slight decrease in electron transfer kinetics on graphene monolayer when compared to bulk graphite, as expressed by the heterogeneous electron transfer rate ( $k^0$ ) measurement of known redox mediators [2]. Another very important issue is degradation/contamination of the crystalline surface upon exposure to the atmosphere. Our recently published data show large differences between the atmosphere-aged and *in situ* cleaved surfaces for both materials are observed, which explains the vast variation of  $k^0$  values in literature [3]. These differences are attributed to oxidation and adsorption of airborne contaminants at the surface exposed to an ambient environment, as determined by X-ray photoelectron spectroscopy. Most importantly, the electrochemical response of semiconducting MoS<sub>2</sub> with an optical band gap of *ca.* 1.2 – 1.8 eV is shown to be strongly dependent on applied potential and incident illumination, promising a wealth of new applications based on vertical heterostructures of graphene and band-gapped 2D materials, as demonstrated by the schematic in Fig.1.

These findings have a direct implication for use of MoS<sub>2</sub> and graphene as electrodes materials and underline the need for an in-depth understanding of electrochemical properties of two-dimensional (2D) materials, which will maximize their potential in electrochemistry-related applications.

# Atomistic Simulations for Designing High-Performance Electrode Materials for Polymer Electrolyte Fuel Cells

Ryosuke Jinnouchi, Kensaku Kodama, Eishiro Toyoda, Kenji Kudo, Naoki Kitano, Naoki Hasegawa and Yu Morimoto

Toyota Central Research & Development Laboratories, Inc.  
41-1 Yokomichi Nagakute, Aichi 480-1192, Japan  
e1262@mosk.tytlabs.co.jp

This presentation shows our recent research activities using atomistic simulations on electrode materials for polymer electrolyte fuel cells (PEFCs). Two topics are presented: DFT calculations on Pt electrocatalysts and molecular dynamics (MD) simulations using force fields on Nafion/Pt interfaces.

In the first topic, after a brief introduction of preliminary applications of DFT to single crystal surfaces [1–4], results on Pt nano-particles are presented [5]. Oxide formations are shown to be initiated by OH and O adsorbates formations at edges and corners of nano-particles as indicated by Fig. 1. Although some meta-stable structures of subsurface  $\text{PtO}_x$  are obtained by the calculations, they are formed only at potentials higher than usual operation potentials of PEFCs, e.g., 0.6–1.0 V (RHE). DFT results on Pt dissolutions indicate that dissolutions are also initiated at edges and corners of nano-particles [6]. To prevent oxidations and dissolutions, which are considered to lower the catalytic activity and durability, respectively, selective substitutions of Pt atoms at edges and corners by Au atoms are suggested to be promising.

In the second topic, MD simulation results are shown on  $\text{O}_2$  transport through Nafion to Pt surface [7]. Simulated results agree well with experimental results on  $\text{O}_2$  diffusivity,  $\text{O}_2$  solvability and limiting current density of ORR and indicate that the Nafion forms a high-density layer near the Nafion/Pt interface causing high interfacial resistivity for  $\text{O}_2$ -transport as shown in Fig. 2.

In summary, atomistic simulations, combined with well-focused experiments, are a powerful and essential approach for designing advanced electrode materials with desired properties for PEFCs.

# Electrochemical Shell-Isolated Nanoparticle-Enhanced Raman Spectroscopy (EC-SHINERS)

Chao-Yu Li, Jin-Chao Dong, Xi Jin, Jian-Feng Li\*

*State Key Laboratory of Physical Chemistry of Solid Surfaces, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen 361005, China*  
*E-mail: Li@xmu.edu.cn*

Surface-enhanced Raman spectroscopy (SERS) is a powerful technique that yields fingerprint vibrational information with ultra-high sensitivity. However, only roughened Ag, Au and Cu surfaces can generate strong SERS effect, and it also in principle excludes to directly study atomically flat single crystal surfaces that cannot effectively support the strong surface plasmon resonance (SPR). The lack of materials and morphology generality has severely limited the breadth of SERS practical applications on surface science, catalysis and electrochemistry.

Shell-isolated nanoparticle-enhanced Raman spectroscopy (SHINERS) was therefore invented to break the long-standing limitation of SERS. In SHINERS, Au@SiO<sub>2</sub> core-shell nanoparticles were rationally designed. The gold core acts as plasmonic antenna and encapsulated by an ultra-thin, uniform and pinhole-free silica shell, can provide high electromagnetic field to enhance the Raman signals of probed molecules. The inert silica shell acts as tunneling barrier prevents the core from interacting with the environment, eg. to avoid contaminated specials or disturbing signals.

Combined with electrochemical methods, SHINERS has already been applied to a number of challenging electrochemical systems, such as hydrogen and CO on Pt(hkl) and Rh(hkl), pyridine and SCN<sup>-</sup> adsorption on Au(hkl). Surface electro-oxidation and-reduction processes at Au(hkl) and Pt(hkl) single crystal electrode surfaces were also been in-situ monitored by electrochemical SHINERS technique. These pioneering studies demonstrate convincingly the ability of EC-SHINERS in exploring correlations between structure and reactivity as well as in monitoring intermediates at the interfaces. The concept of shell-isolated nanoparticle-enhancement is being applied to other spectroscopies such as infrared absorption, sum frequency generation and fluorescence.

# Molecular Insight into Wetted Oxide Surfaces and Oxygen Electrocatalysis

Kelsey A. Stoerzinger<sup>1</sup>, Wesley T. Hong<sup>1</sup>, Yueh-Lin Lee<sup>2</sup>, Livia Giordano<sup>2</sup>, Yang Shao-Horn<sup>1,2</sup>

<sup>1</sup>*Department of Materials Science & Engineering*, <sup>2</sup>*Mechanical Engineering Department*  
*Massachusetts Institute of Technology, 77 Massachusetts Ave. Cambridge, MA 02139 USA*  
*kstoerz@mit.edu*

Oxide materials are critical components in electrochemical applications such as gas sensing and catalysis of the oxygen reduction and evolution reactions (ORR and OER) in fuel cells and electrolyzers.[1] In each of these applications, the surface chemistry of the oxide is directly influenced by the presence of water molecules—in the atmosphere or an aqueous solution—that govern the hydroxylation and charge of surface.[2] The binding of hydroxyl groups and other oxygenated species on oxides surfaces has been proposed to govern oxygen electrocatalysis[3] and explain the hydrophilic/hydrophobic nature of oxide surfaces.[4] Unfortunately, directly measuring hydroxylation and surface adsorbates in water and correlating these species to wetting and catalytic activity is challenging. Utilizing recent advances in X-ray photoelectron spectroscopy (XPS) at near-ambient pressure (NAP-XPS), we quantitatively assess surface hydroxylation and adsorption of water on  $\text{LaMO}_3$  epitaxial thin films ( $M = \text{Cr, Mn, Fe, Co, Ni}$ ).[5] The affinity toward hydroxylation, coincident with strong adsorption energies calculated for dissociated water and hydroxyl groups by density functional theory (DFT), leads to strong H-bonding in wetting and can inhibit catalysis of the ORR. We further test this correlation through manipulating the transition metal valence and oxide electronic structure via substitution of  $\text{La}^{3+}$  with  $\text{Sr}^{2+}$  in the series  $\text{La}_{(1-x)}\text{Sr}_x\text{MnO}_3$ , exploring the relation between band structure and work function with activity and wetting.

For some oxides, the interaction with water and associated ions can be observed by well-defined redox peaks, such as  $\text{RuO}_2$ —one of the most active catalysts of the OER.[6] We have studied the redox features of oriented  $\text{RuO}_2$  films, where the unique surface structures dictate the interaction with water and its ions ( $\text{H}^+$ ,  $\text{OH}^-$ ), as well as the ability of the active Ru sites to change valence state. The ease and extent of Ru redox impacts the specific OER activity of different crystallographic orientations,[7] motivating further work on in situ spectroscopy and theory to understand and design more active catalyst surfaces.

The insights obtained from study of these epitaxial surfaces build fundamental understanding of the mechanisms of oxygen electrocatalysis, as well as guide the rational design of high surface area oxide catalysts for electrochemical conversion and storage.

# CO<sub>2</sub> electroreduction products and intermediates in organic solvents

Marta C. Figueiredo, Marc T. M. Koper  
Leiden Institute of Chemistry, Leiden University,  
PO Box 9502, 2300 RA Leiden, Netherlands  
*m.c.costa.figueiredo@lic.leidenuniv.nl*

CO<sub>2</sub> amounts are increasing continuously in the atmosphere generating an issue of global concern, as CO<sub>2</sub> is known to be one of the major contributors to the greenhouse effect [1]. Several methods for CO<sub>2</sub> sequestration [2] (capture and storage) have been studied and developed in the last decades but this technology still divides the scientific opinion around the world, as the storage of CO<sub>2</sub> in container under sea water do not look as an appealing long term solution [3]. In this sense, the electrochemical conversion into something useful (like fuels or chemicals) is probably of one the most promising options.

The electrochemical reduction of CO<sub>2</sub> has, in fact, been studied intensively over the last decades [4]. It is known that its products depend on the many factors like supporting electrolyte, electrode material, applied potential. In aqueous solutions the possible products are CO, formic acid and hydrocarbons such as methane, ethane and ethylene [5]. However, in water, CO<sub>2</sub> reduction has as competing reaction the hydrogen evolution that occurs in the same potential range. Yet, in organic solvents hydrogen evolution can be avoided. Organic solvents also present other important advantages when compared with aqueous media such as higher solubility of CO<sub>2</sub>, larger cathodic potential window and stabilization of important reaction intermediates such as CO<sub>2</sub> anion radical [6, 7]. It has been described that in non-aqueous solvents, the CO<sub>2</sub> electroreduction mechanism follows three different paths: by self-coupling of the anion radical with the formation of oxalate; through oxygen-carbon coupling of CO<sub>2</sub><sup>•-</sup> with CO<sub>2</sub> having CO and CO<sub>3</sub><sup>2-</sup> as products and, and CO<sub>2</sub><sup>•-</sup> protonation by residual water to yield formate as main reaction product [6]. Despite all the efforts on this subject, the real nature of the intermediates and the mechanism of the CO<sub>2</sub> reduction on non-aqueous solvents is not fully understood and a wide range of information can be found in the literature [8, 9].

In this work, we persecute a further understanding on the reduction mechanism of CO<sub>2</sub> in acetonitrile at copper electrodes. Copper electrodes were chosen due to their known reactivity for CO<sub>2</sub> in aqueous media [10]. The experiments were performed by using in situ Fourier Transformed infra-red spectroscopy (FTIR) in order to get insights on the products and intermediates of the reaction and its dependence on the applied potential. The results show that carbonates are the main product of this reaction and, for the first time, CO was identified by FTIR in acetonitrile media. Water contents and the solvent decomposition are shown to heavily influence the reaction mechanism and the nature of the products.

# Observation of Gas Structures at the Interface between a Hydrophobic Electrode and Water Using Atomic Force Microscopy

Yi-Hsien Lu, Chih-Wen Yang, Chung-Kai Fang, Hsien-Chen Ko and Ing-Shouh Hwang  
*Institute of Physics, Academia Sinica,  
Taipei 11529, Taiwan  
zonslan@gmail.com*

The microscopic picture at the vicinity of the electrode-solution interface is of fundamental and extreme importance to the electrochemical processes. The dissolved gases, with only  $\sim 0.8$  mM equilibrium concentration in water (standard conditions), have been attracted only limited attention. However, experimental evidence is growing in support of the critical role of dissolved gases at water interfaces, and particularly for hydrophobic/water interfaces.

In this work, we use high sensitivity atomic force microscopy (AFM) modes, including the frequency modulation (FM) and the PeakForce (PF) modes, to investigate the interface between water and a common hydrophobic electrode, highly ordered pyrolytic graphite (HOPG). We show that dissolved gas can accumulate and form an ordered layer at HOPG/water interface, even when the gas concentration is well below the saturation level<sup>[1-3]</sup>. When the gas concentration is high, various gas structures can be observed, including ordered adlayer(s), disordered pancake-like layer, and cap-shaped structures (nanobubbles). Since some of the common used electrode, such as gold, and graphite, have a certain degree of hydrophobicity, the effect of dissolved gas at the interface should be taken into account in electrochemical systems.

Figure 1 An AFM image of the HOPG/water interface showing an ordered layer of gas molecules when the gas concentration is low.

Figure 2 AFM Images of HOPG-water interfaces after the nitrogen (a) and oxygen (b) supersaturated water is deposited.

# **Glow Discharge Optical Emission Spectroscopy Used for Film Formation studies on Graphite Electrodes**

Niloofer Ghanbari, Thomas Waldmann, Michael Kasper, Peter Axmann, Margret Wohlfahrt-Mehrens  
*Zentrum für Sonnenenergie- und Wasserstoff-Forschung, Baden-Württemberg,  
Helmholtzstrasse 8, D-89081 Ulm, Germany  
niloofer.ghanbari@zsw-bw.de*

Glow discharge optical emission spectroscopy (GD-OES) was introduced by Grimm in 1968<sup>1</sup>. It provides an elemental depth profile analysis of solid samples. Sensitivity to light elements such as Li and H, mitigated lattice damage, fast analysis, quantification of the recorded elemental intensity and the possibility to perform high resolution depth profiling as deep as ~100µm gives GD-OES some specific strengths compared with similar analytical methods (SIMS, XPS, and AES). Therefore, it is considered as a powerful tool in analyzing Li-ion battery electrodes since it presents a more clear view of “surface” and bulk and allows also a quantified analysis of surface inhomogeneities.

A more detailed understanding of the contribution of individual electrode reactions to the ageing of complete lithium ion batteries is absolutely necessary, in order to optimize both cell chemistry as well as battery management systems.<sup>2</sup> Post mortem analysis of lithium ion cells provides an insight into aging phenomena under different operation conditions, and leads to improving cell design and ensuring safe operation. Li deposition (plating) on graphite electrodes, which could take place upon anode polarization at low temperature and/or high cycling rate, is a crucial phenomenon with intense impact on cell capacity fading and safety. The study aims on the analysis of the film formed on graphite anodes under Li deposition conditions based on quantified depth profile analysis using GD-OES.

The GD-OES method is developed for graphite-based electrodes and calibrated for selected elements using lab coated samples. Beside model graphite electrodes, which have been cycled under well controlled conditions, electrode samples from “fresh” and aged commercial graphite/NMC cells have been investigated. The commercial cells have been aged at different C rates and low and high temperature (5°C and 45°C). The depth profile analysis shows low carbon and high Li content in the first ~10µm from the surface. These two elements help defining a border between “surface film” and “bulk”. The GDOES analysis shows significant differences in the depth profiles for lithium, carbon and phosphorous content. The results of various electrodes aged at different conditions are compared with a fresh graphite electrode of the same cell type and model electrodes for better comparison. This detailed analysis accompanied by electrochemical data, SEM imaging and data from conventional post mortem analysis reveals different mechanisms and localization of Li deposition on graphite during cycling with high C-rates at low and high temperatures.

A redox conducting poly[*meso-N,N'*-Bis-(salicylidene)-2,3-butanediaminonickel(II)] was synthesized by electrochemical polymerization. The resulting polymer film was highly conducting and stable with respect to potential multicycling under cyclic voltammetry conditions. The properties of the polymer were very promising for devising a new electrode material for supercapacitors. The UV-visible, FT-IR-ATR, and low-temperature ESR in situ spectroelectrochemical experiments unraveled both the charge transfer and polymerization mechanism of this polymer. With the low-temperature ESR measurements short-living paramagnetic transient species were detected and identified as bisphenolic radical cations. Moreover, structures responsible for the charge transfer in the polymer film were modeled with the quantum chemistry calculation method using density functional theory (DFT). The neutral polymer, bisphenolic dication, and bisphenolic radical cation were simulated as basic polymer building blocks consisting of two monomer units. Geometry of these structures in the ground state was DFT optimized with the B3LYP functional and the 6-31G basis. The excited state parameters were calculated on the ab-initio level by the time-dependent DFT (T-D DFT) method. Similarly as for the geometry optimization, the same B3LYP functional and basis set were applied. All the methods used were implemented in the Gaussian 09 software package [1].

**Abstract**

With today's great demand for energy, energy storage and its materials have become one of the most important technologies. Lithium ion batteries (LIBs) have high energy density and low environmental impact, and thus have drawn the most attentions among various energy storage technologies. Developing high capacity LIBs is the key for commercializing electrical vehicles and smart grids. The lithium-rich composite-layered oxide,  $x\text{Li}_2\text{MnO}_3 \cdot (1-x)\text{LiM}'\text{O}_2$ , where  $\text{M}'$  is transition metals, is a promising cathode material with high capacity. However, it has some native fatal weaknesses, including: (1) high initial irreversible capacity, (2) quick capacity fading, and (3) low rate capability, which greatly limit its range of applications. In this work, *ab initio* calculations based on density function theory were employed to simulate the lattice stability of  $x\text{Li}_2\text{MnO}_3 \cdot (1-x)\text{Li}(\text{Ni}_{1/3}\text{Mn}_{1/3}\text{Co}_{1/3})\text{O}_2$  composite-layered cathode materials. The atomistic models based on both monoclinic (C2/m) and rhombohedral (R3m) for the pristine  $\text{Li}_2\text{MnO}_3$  and  $\text{Li}(\text{Ni}_{1/3}\text{Mn}_{1/3}\text{Co}_{1/3})\text{O}_2$  phases were built. In addition, the atomistic models of composite-layered oxide with combinations of different individual structures and compositing ratios were examined. The optimized composite-layered oxide exhibits pseudo-rhombohedral or monoclinic-like structure, which agrees closely with experiments. The calculated X-ray diffraction patterns based the optimized structure also agrees closely with experiments. These findings clearly identify the fact that the major mechanism of capacity fading is lattice distortion. Finally, the convex hull calculation of lithiated composite-layered oxides was also performed to investigate the mechanism of Li-ion intercalation during charging/discharging. This paper proposes fundamental understandings of the  $x\text{Li}_2\text{MnO}_3 \cdot (1-x)\text{LiM}'\text{O}_2$  composite-layered oxides based on theoretical computations, which can provide guidance for developing novel high capacity cathode materials.

# In-situ monitoring of metal dissolution during anodisation of Al and Ti

J. P. Kollender<sup>1</sup>, A. I. Mardare<sup>1</sup>, A. W. Hassel<sup>1,2</sup>

<sup>1</sup>*Institute for Chemical Technology of Inorganic Materials*

*jan.kollender@jku.at*

Aluminum and titanium are non-noble metals which are spontaneously reacting with water or oxygen forming aluminum oxide ( $\text{Al}_2\text{O}_3$ ) and titanium dioxide ( $\text{TiO}_2$ ). These thin passive layers are protecting the metals from further corrosion. The thickness of the passive layers can be artificially increased for improved corrosion and wear resistance using an electrochemical process called anodisation.

Many aspects of the oxide growth process during anodisation of Al and Ti have been investigated in the past. The most widely used model for description of the oxide growth mechanism during anodisation is the high field model [1]. One parameter that cannot be described by the high field model or any other existing model is the metal dissolution during oxide growth. Until now the metal dissolution during anodisation has also never been experimentally observed or quantified. To investigate this phenomenon a flow-type scanning droplet cell microscope (FT-SDCM) [2] which is directly coupled to inductively coupled plasma mass spectrometry (ICP-MS) was developed. This technique allows time resolved in-situ analysis of metal dissolution during anodisation.

Using this technique we investigated the time and potential dependent dissolution of Al during anodisation on individual spots (see left image) and during stepwise potential growth on a single addressed spot (see right image). During all experiments it was observed that an overshoot in Al dissolution occurs during the initial stage of oxide growth. After the initial oxide growth the dissolution rate stabilized into a constant plateau (transpassive dissolution) for all investigated potentials. It was further observed that the transpassive dissolution rate in case of Al linearly depends on the applied potential. In case of Ti an overshoot in metal dissolution during initial oxide growth was also observed, but at a significantly lower rate. Unlike Al, Ti showed no significant transpassive dissolution, indicating a much higher stability of titanium dioxide compared to aluminum oxide.

marueda@us.es

The combination of electrochemical methods with modern in-situ Fourier infrared techniques can provide microscopic information about the orientations and interactions of adsorbed molecules on electrode surfaces [1]. The adsorption of thymine on electrodes is interesting because as a DNA base (complementary of adenine) this molecule plays important roles in genetic expression and replication in well organised biological interfaces, which presents similar characteristics as the electrode interfaces. The molecule can adopt different tautomeric forms, depending on the pH of the solution but the preponderance of them at the interfaces can be affected also by the electric field. The study of the influence of pH and electric potential on the tautomeric equilibrium can have epigenetic implications because it is known that unstable tautomeric forms can induce unpaired bases interactions which seem to be related with some illness.

Thymine adsorption on gold electrodes has previously been studied and different electric potential regions were identified at which physical or chemical adsorptions take place. Under some conditions characteristic transition of phase peaks were observed delimiting potential regions with different organised surface structures [2,3]. It was proposed that thymine gets deprotonated when adsorbed on the electrode, even at low pH values. It is known that in solution two thymine forms are related by one acid-base equilibrium ( $pK_a$  value 9.5) but each of them can present also enol-imino tautomeric forms [4].

In this communication, the advantages of the ATR-SEIRAS technique to determine the structures at electrode surfaces are exploited in order to establish the nature of the different organisations of thymine on gold electrodes as a function of pH and potential. Experiments have been performed in the pH range 1 to 12 in perchlorate and either perchloric acid/or sodium hydroxide solutions, using  $H_2O$  and  $D_2O$  as solvents. Thin-film gold electrodes prepared by sputtering were used as working electrodes and some complementary electrochemical and SNIPTIRS experiments have been performed using Au(111) electrodes.

The analysis of the characteristic bands in the  $1200$  to  $1800\text{ cm}^{-1}$  spectral region is used to identify the two tautomers of the deprotonated molecule. The assignments of the most stable tautomers are confirmed by DFT calculations that optimise the geometry of the adsorbed molecule on Au(111) surfaces. A semi-quantitative analysis of the orientation of each tautomer as a function of potential has also been performed on the base of the ratio between two characteristic stretching signals in the  $2500$  to  $3500\text{ cm}^{-1}$  spectral region. The results are discussed in relation to the effect of the electric field on the permanent dipole of the tautomeric adsorbed forms.

dywu@xmu.edu.cn*

To study water in electrochemical interfaces plays important roles not only the most usual solvent but also energy source and environment fields. Hydrogen evolution reaction is one of the most fundamental electrochemical reactions in electrode/aqueous solution interfaces and strongly depends on experimental conditions, such as electrode materials, light irradiation, and containing organic molecules electrolytes [1]. The reaction mechanisms elucidated before are all based on the two-step mechanism of Volmer, and Tafel or Heyrovsky reactions so far. Nanoscale noble metals display special catalyst in light splitting water reaction for its high efficiency and environment friendly and the surface plasmon resonance in the visible region.

In this paper, we proposed a novel intermediate for photocatalytic hydrogen evolution reaction on silver and gold cathodes by a combining study of surface spectroscopy and quantum chemical calculations with the density functional theoretical methods and metallic cluster models. Water and hydronium ion adsorbs on metal cathodes with an embedded layer of water (Figure 1) [2-4].

According to the calculated results, water molecules approach to metal cathodes by the hydrogen atoms. As for hydrated protons, the surface electron-hydronium ( $e^- \cdots H_3O^+$ ) ion pair can be formed on the metal cathodes. Under the irradiation of light, the surface bound electrons are excited and devote to the reduction reaction, with a structural relaxation from Eigen-type proton to hydrated hydrogen atoms, i.e., a stepwise pathway as Eigen  $\rightarrow$  Zundel  $\xrightarrow{+e^-}$  H. The relaxation process of the  $e^- \cdots H_3O^+$  ion pair happens in the solution side rather than hydrogen directly at adsorbed sites on the surface of silver/gold nanoparticles. Finally they recombined to hydrogen molecules. Additionally, we calculated surface-enhanced Raman scattering (SERS) spectra of adsorbed water molecules and the interfacial  $e^- \cdots H_3O^+$  ion pairs, indicating the SERS spectroscopy is a powerful technique to characterize surface species in photocatalytic hydrogen evolution reactions.

# Electrochemical Tip-Enhanced Raman Spectroscopy (EC-TERS)

Bin Ren, Zhi-Cong Zeng, Sheng-Chao Huang, Teng-Xiang Huang, Jin-Hui Zhong, Mao-Hua Li, Xiang Wang

*State Key Laboratory of Physical Chemistry of Solid Surface, Collaborative Innovation Center of Chemistry of Energy Materials (iChEM), Department of Chemistry, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen 361005, China  
E-mail: bren@xmu.edu.cn*

Tip-enhanced Raman spectroscopy (TERS) can not only provide very high sensitivity but also high spatial resolution, and has found applications in various fields, including surface science, materials, and biology. Most of previous TERS studies were performed in air or in the ultrahigh vacuum. If TERS study can be performed in the electrochemical environment, the electronic properties of the surface can be well controlled so that the interaction of the molecules with the substrate and the configuration of the molecules on the surface can also be well controlled.

However, the EC-TERS is not just a simple combination of electrochemistry with TERS, or the combination of EC-STM with Raman. It is a merge of STM, electrochemistry and Raman spectroscopy, and the mutual interference among these techniques makes the EC-TERS particularly challenge: the light distortion in EC system, the sensitivity, the tip coating to work under EC-STM and retain the TERS activity and cleanliness.

We designed a special spectroelectrochemical cell to eliminate largely the distortion of the liquid layer to the optical path. We have been able to obtain TER spectra of reasonably good signal to noise ratio for surface adsorbed molecules under electrochemical potential control. For example, potential dependent TERS signal have been obtained for adsorbed aromatic thiol molecule, and much obvious signal change compared with SERS has been found, manifesting the importance of EC-TERS to reveal the interfacial structure of an electrochemical system. Furthermore, we are able to detect the potential dependent surface photochemical reaction on the single crystal surface. More systems will be discussed during the talk.

The success in constructing the EC-TERS offers us an opportunity for investigation of electrochemical interfaces by vibrational spectroscopy with unprecedented spatial resolution and molecular fingerprints.

# Electrochemical interrogation of the structure of self-assembled monolayers on nanofabricated metallic nanowires

D. William A. Morton, A. Giles Davies, Christoph Wälti  
*School of Electronic and Electrical Engineering, University of Leeds*  
*Woodhouse Lane, Leeds LS2 9JT, UK*  
*mt09dwm@leeds.ac.uk*

With the recent advancement of ultrahigh-resolution patterning techniques, such as electron beam and extreme ultraviolet lithography, now enabling the fabrication of devices with typical feature sizes significantly less than 100 nm, nanostructured metallic structures are becoming increasingly important in a number of areas. Such structures have proven to be particularly popular as interfaces between solid-state devices and molecular or biological molecules. The nanostructured electrodes are often functionalized with self-assembled monolayers (SAMs), for instance to attach biological molecules. Very popular examples where such functionalized metallic nanostructures are employed are nanowire-based biosensors.

While the fabrication of the nanostructures as well as their electronic properties are relatively well understood, the understanding of the influence of the nanostructure on the structure and order of the SAM is still in its infancy. Any inconsistency in the properties of the SAM, such as increased leakage current due to disorder in the SAM, will be significant, and hence it is essential to understand the impact of the nanostructure on the assembly and structure of SAMs.

To establish a more detailed understanding of the impact these nanostructures have, we have fabricated arrays of gold nanowires of different dimensions using electron beam lithography (EBL) (nanowire widths 40 – 100 nm, array spacings 300 nm – 3 µm). These nanowire arrays were functionalized with well-packed SAMs of mercapto-alkanes of varying length. Through careful definition of the width and height of the nanowires, the impact of the edges of the metallic structures (the “edge effect”), which induce disorder in the SAM as the SAM formed on sharp topological features of the structures is not well-packed, can be maximized. Electrochemical analytical techniques are very well suited to interrogate this disorder in the SAM. We used a combination of cyclic voltammetry (CV), electrochemical impedance spectroscopy (EIS) and chronoamperometry (CA) in Faradaic solutions to understand qualitatively the level of disorder in the monolayer as a function of nanowire dimensions and SAM molecule length. In addition, we used atomic force microscopy (AFM) and scanning electrochemical microscopy (SECM) to image directly and quantitatively analyze this disorder.

We found that the greatest disorder was induced in the SAM on the smallest fabricated nanowires (40 nm wide and 30 nm high), where edge effects are most prominent. This was established through equivalent circuit, such as Randles circuit, analysis, where a greater disorder was associated with a higher concentration of pinhole-like defects in the SAM, manifested in increasing leakage current. We found the shortest SAM molecule studied ( $\text{CH}_3(\text{CH}_2)_8\text{SH}$ ) exhibited the greatest disorder on all nanowire dimensions, and the leakage current was found to decrease with increasing SAM molecule length. Negligible leakage current was measured for SAMs formed from molecules with lengths above a certain threshold. These findings are corroborated by AFM and SECM imaging.

SEM and AFM image of an array of EBL patterned nanowires.

# Electrochemical Adsorption and Surface-Enhanced Raman Spectroscopy on Nanostructured Electrodes

De-Yin Wu, Yuan-Fei Wu, Zhong-Qun Tian

Surface-enhanced Raman spectroscopy (SERS) with high detection sensitivity is a powerful tool for characterization of probe molecules on electrode surfaces. High quality Raman signals provide not only adsorption orientation but also chemical bonding interaction between molecules and electrode surfaces with applied potentials. In electrochemical interfaces, the photo-driven charge transfer can happen at the proper excitation light to significantly enhance Raman intensities along selectively vibrational modes. Thus the SERS signals of these specific vibrational probes can be used to explore low-lying excited states and the complex interaction between electrode surfaces and different lights under applied potentials. Pyridine is one of the best typical modeling molecules in electrochemical SERS fields. In previous studies, we have investigated the SERS of pyridine adsorbed on silver and gold and other transition metal electrodes dependent on the potential energy surface of excited charge transfer states. There are four vibrational modes display strongly potential-dependent SERS effect on the surface electronic structures and chemical adsorptions. For example, when pyridine adsorbed on a silver electrode, there are four strong Raman peaks at 1008, 628, 1590, and 1215  $\text{cm}^{-1}$  arising from the ring breathing mode ( $\nu_1$ ), the ring deformation ( $\nu_{6a}$ ), and the ring C-C stretching vibration ( $\nu_{8a}$ ) and the C-H in-plane bending vibration ( $\nu_{9a}$ ) at -0.6 ~ -0.8 V vs SCE.

To understand the photo-driven charge transfer mechanism in electrochemical SERS, we have calculated the potential energy curves of the low-lying excited states on the basis of density functional theoretical (DFT) method. Specifically, the hybrid functional approach B3LYP was combined with the basis sets of 6-311+G\*\* for elements C, N, O, S and H, as well as LANL2DZ pseudopotential basis set for silver and gold. The time-dependent DFT (TDDFT) was used to calculate the excited states, which chemically contribute to the Raman intensity enhancement. The charge transfer enhanced mechanism also depends on metal property, such as silver and gold electrodes and the electric field in double electric layers. We discuss the electric and vibrational Stark effect on the Raman signal. Next, we further explore the anchor group effect on the charge transfer enhancement mechanism in 4-mercaptopyridine adsorbed on silver electrodes. Our result showed that the charge transfer direction from the probe molecule to silver surfaces when 4-mercaptopyridine binds to silver through its thiol sulfur. However, when pyridine ring nitrogen also approaches to the silver surfaces. The charge transfer energy significantly decreases to ~2.0 eV, matching to the photonic energy used in usual SERS measurements. In the case, the charge transfer mechanism may be switched from surface silver to pyridine ring moiety. Therefore, we suggested the electrochemical SERS can be used to explore some excited states related to the photo-driven charge transfer process.

Synthesis of highly-ordered nanostructures of valve metal oxides has recently attracted huge scientific and technological interest motivated by their possible use in many applications. The nanoporous Al<sub>2</sub>O<sub>3</sub> – most established member of this group of materials – has been prepared by anodic oxidation of Al under suitable electrochemical conditions two decades ago into perfectly ordered, honeycomb-like porous structures (1). Owing to the flexibility of the pore diameter/length and the relative ease of the Al<sub>2</sub>O<sub>3</sub> dissolution, its porous membranes have been since then widely used as template material of the choice for a range of materials (2-4).

It is the TiO<sub>2</sub> that has received the highest attention after Al<sub>2</sub>O<sub>3</sub> motivated by its range of applications, including photocatalysis, water splitting, solar cells and biomedical uses. Very significant research efforts have led to reproducible synthesis of self-organized TiO<sub>2</sub> nanotube layers by means of anodic oxidation, during which the starting Ti substrate is converted into highly-ordered nanotubular layer by anodization in suitable electrolytes (5-7). Although advancements in the anodic synthesis of self-organized TiO<sub>2</sub> nanotube layers have been presented over past years (8), as shown in Fig. 1a, the degree of ordering has not reached so far the level known from porous alumina (1). Numerous factors influence the ordering and the homogeneity of the TiO<sub>2</sub> nanotube layers.

In the presentation, we aim to demonstrate significant advancements in the ordering of anodic TiO<sub>2</sub> nanotubes compared to known state-of-art. Utilizing AFM, SEM and optical measurements, we will show how to obtain via tailored anodization protocols a very decent degree of uniformity and homogeneity of the nanotube layers, as shown on Fig. 1b (9). Moreover, based on SEM, EBSD and TEM measurements, we will demonstrate how the Ti grain structure influences the lateral uniformity of the nanotube layers (10).

Fig. 1 Anodic TiO<sub>2</sub> nanotube layers ordered on a smaller (a) and larger (b) scale.

Nowadays, ethanol has an increasing interest for its use as a fuel in the fuel cell technology, due to some environmental and energetic advantages respect to similar small alcohols molecules. In addition, the higher activity for ethanol oxidation observed in alkaline solutions together with the appearance of new alkaline membranes have triggered the studies at higher pHs with the aim of improve the selectivity to CO<sub>2</sub>. As a catalyst, platinum presents the best behavior among pure metals this reaction. However, the higher cost of the material has induced the use of nanoparticles, which optimizes the active area of catalyst using lower amounts of platinum.

It is well-known the dependence of ethanol oxidation reaction with the surface structure orientation of platinum. In acidic solutions, (100) surfaces favors the C-C bond scission producing the complete oxidation to CO<sub>2</sub>, in spite of the CO formation that poison the catalytic surface. In (111) domains, only the incomplete oxidation to acetic acid is observed [1]. These tendencies are also observed for preferentially oriented platinum nanoparticles [2]. To promote the CO<sub>2</sub> formation and to facilitate the oxidation of CO, foreign atoms are adsorbed on the Pt surface, transferring to the CO molecule the oxygen group necessary to complete the oxidation until CO<sub>2</sub> [3]. Additionally, if larger loadings of nanoparticles are confined in a small support, aggregation problems can occur, which leads to lower catalytic activities [4]. For this reason, it is important control the nanoparticles dispersion around the support for ensure the correct behavior of the catalyst.

In this communication, the ethanol oxidation reaction is studied in shape-controlled platinum nanoparticles with several adsorbed atoms, trying to obtain the better combination nanoparticle orientation/adatom for achieving the highest activity at lower potentials. In addition, the dispersion of nanoparticles is also controlled for prevent aggregation problems. Electrochemical techniques (cyclic voltammetry and chronoamperometry) are used for characterize the reactivity for the ethanol electrooxidation.

**Figure 1:** (A) Difference between a non-disperse (a) and disperse (b) nanoparticles deposit in a gold support. (B) Cyclic voltammetry response for (111) Pt nanoparticles with different Sn coverage in 0.2 M ethanol + 0.5 M H<sub>2</sub>SO<sub>4</sub> at 0.02 V s<sup>-1</sup>.

Room temperature ionic liquids (RTILs) are promising electrolyte materials for Li ion batteries and other electrochemical devices due to high ionic conductivity and wide electrochemical windows. It has been reported that the cathodic decomposition potential of the FSA-based RTIL is less negative than that of TFSA-based RTIL when Li salt is added,<sup>1</sup> despite the similar chemical structures of FSA and TFSA anions (Fig.1). A mechanism for stabilization of the FSA-based RTIL on the electrode involving an interfacial structure of the RTIL has been proposed;<sup>1</sup> however, direct observation using spectroscopic techniques is required to understand the details. Surface-enhanced infrared absorption spectroscopy (SEIRAS) that can selectively probe solid/liquid interfaces is suited for this purpose as represented in our recent studies on the potential-dependent behavior of a pure TFSA-based RTIL on an Au electrode using this method.<sup>2</sup> In the present work, we investigated the effect of Li ion on the potential-dependent structure of [BMIM][FSA] (Fig.1) on an Au electrode by using SEIRAS as a function of Li<sup>+</sup> concentration.

SEIRAS experiments have been performed on an Au thin film electrode chemically deposited on a Si prism in a vacuum-compatible glass cell. The electrode potential was controlled by a potentiostat against a Pt quasi-reference electrode and corrected by the redox potential of Fc/Fc<sup>+</sup> couple. LiFSA is added to [BMIM][FSA] to control the concentrations of Li<sup>+</sup>. SEIRAS measurements have been performed during potential scans where the deposition of Li does not occur.

Figure 2 shows potential-dependent SEIRA spectra of the [BMIM][FSA]/Au electrode at various Li concentrations. For pure [BMIM][FSA] (Fig. 2a), negative absorption bands at 3200-3000 cm<sup>-1</sup> assigned to C-H stretch modes of imidazolium ring of the cation  $\nu(\text{CH})_{\text{ring}}$  and positive bands at 3000-2840 cm<sup>-1</sup> assigned to those of alkyl group  $\nu(\text{CH})_{\text{alkyl}}$  are observed at negative potentials. This indicates, as reported previously for [BMIM][TFSA],<sup>2</sup> that the orientation of the imidazolium ring changes from a perpendicular orientation to a more flat one on the basis of the surface selection rule in SEIRAS: the vibrations that yield oscillating dipoles perpendicular to the surface are selectively observable. For [BMIM][FSA] with 10 % Li salt (Fig. 2b), on the other hand, negative absorption bands of both  $\nu(\text{CH})_{\text{ring}}$  and  $\nu(\text{CH})_{\text{alkyl}}$  are observed at negative potentials, suggesting that BMIM cations move further away from the electrode although electrode is negatively charged. A possible interpretation is that decomposition products of [BMIM][FSA] formed at negative potentials inhibit cations from approaching to the electrode and dissolve at positive potentials. For [BMIM][FSA] with 20 % Li salt (Fig. 2c), very small absorption bands of  $\nu(\text{CH})_{\text{ring}}$  and  $\nu(\text{CH})_{\text{alkyl}}$  suggest that BMIM cations exist much further away from the electrode than in the case of 10 %. Potential-dependent behavior of anions and solvation of Li<sup>+</sup> will be also reported in the presentation.

myaguchi@cat.hokudai.ac.jp

## I. Introduction

The electrocatalytic oxidation of formic acid has been the subject of intense investigations due to its importance in understanding the oxidation of small organics utilized as fuels in low-temperature fuel cells. It is widely accepted that formic acid is oxidized through the so-called ‘dual-pathway’ mechanism; the direct pathway via a reactive intermediate, and the indirect pathway via CO. The reaction kinetics and the chemical nature of the reactive intermediates, however, have been remained uncertain. Joo et al.<sup>[1]</sup> was the first to investigate the formic acid oxidation on Pt over various electrolyte pH, from acid through alkaline, and demonstrated that formate ion is the dominant reactant even in acidic media (note that the  $pK_a$  of formic acid is 3.75). Au is less active than Pt and thus the formic acid/formate oxidation takes place moderately, which allows us to study the reaction mechanism more in detail with no interference from the poisoning species (CO). In this work, we have systematically examined the formic acid oxidation on Au under wide range of electrolyte pH by cyclic voltammetry and *in-situ* attenuated total reflection-surface enhanced infrared absorption spectroscopy (ATR-SEIRAS) with aiming for identifying the nature of the reactive intermediates. The results are compared with those obtained on Pt, which would help reveal the origin of the difference in catalytic activity.

## II. Experimental

All electrochemical and ATR-SEIRAS measurements were carried out in conventional three-electrode glass cells at room temperature. Phosphate buffer solutions were used as the supporting electrolytes. The working electrodes were the polycrystalline Au and Pt disk electrodes for the RDE experiments and the chemically deposited polycrystalline Au and Pt thin-film electrodes for the ATR-SEIRAS experiments. A large platinum foil served as the counter electrode, and the reference electrode was the silver/silver chloride electrode (Ag/AgCl/sat. KCl). All potentials were converted to RHE scale.

## III. Results and Discussion

On Au, an oxidation peak was observed at  $\sim 1.0$  V in both the forward and the following backward scans. An additional peak was also observed at  $\sim 1.5$  V as a shoulder only in the forward scan. In Fig. 1, the current densities (at 1.0 V in the backward scan) for the oxidation of 0.5 M formic acid/formate in 0.1M phosphate buffer solutions are plotted against the electrolyte pH. It exhibits a volcano-shaped dependence and the maximum current density is achieved at pH  $\sim 5$ . In the ATR-SEIRA spectra, the band attributed to the adsorbed bridge-bonded formate (b-HCOO<sub>ads</sub>) was observed at  $1330\text{ cm}^{-1}$ . The integrated intensity of this band displayed similar pH dependence to Fig.1. The drastic reduction of current density in alkaline region seems to be related to the strong adsorption of  $\text{HPO}_4^{2-}$ . Considering the effect of anion adsorption from the electrolyte, other buffer solutions composed of weakly adsorbed anions were employed. It was found that the point where the current density or the band intensity of b-HCOO<sub>ads</sub> starts to decrease was extended toward higher pH region. Overall, it turns out that the current density is associated with the b-HCOO<sub>ads</sub> band intensity, suggesting that, unlike on Pt<sup>1</sup>, the adsorbed bridge-bonded formate plays a significant role as a reactive intermediate or a promotor in the dominant reaction pathway on Au, which eventually would result in the difference between Au and Pt as a catalyst.

**Fig.1.** pH dependence of the current density for formic acid/formate oxidation on a gold RDE in phosphate buffer solution.

The oxygen reduction reaction (ORR) occurs at the cathode in polymer electrolyte fuel cells (PEFCs) and its sluggish kinetics is one of the limiting factors for the performance of PEFCs. Although platinum-based ORR catalysts are used in the state-of-the-art PEFCs, they still have high overpotential (>200 mV). In nature, on the other hand, it is known that enzymes such as multi-copper oxidases catalyze ORR with almost no overpotential (ca. 20 mV), where a catalytic active center with a multinuclear copper complex is found.<sup>[1-2]</sup> Although these enzymes show such high ORR activity, enzymes are not suitable for use in practical PEFCs since enzymes are easily denatured and their footnotes are large, resulting in low stability and low current density output, respectively. Thus, it is highly desirable to design and develop robust artificial ORR catalysts with electrocatalytic properties that are similar to those of the enzymes.<sup>[3]</sup>

Here, we present our *in situ* X-ray absorption fine structure (XAFS) spectroscopic studies on a dinuclear copper(II) complex of 3,5-diamino-1,2,4-triazole, Cu-Hdatrz (Figure 1)<sup>[4,5]</sup> under catalytic conditions. Cu-Hdatrz is one of the most active copper-based catalysts for ORR in basic solution<sup>[5]</sup> and its mechanistic studies would allow us to gain insights into designing highly active bio-inspired catalysts. Our *in situ* XAFS measurements revealed that the electron transfer from a Cu<sup>I</sup> species to O<sub>2</sub> was faster under basic conditions than that under the neutral condition.<sup>[6]</sup> This result indicated that deprotonation occurred in the triazole ligand and then a highly active ORR species was formed under basic conditions. The deprotonated structure of the Cu<sup>I</sup> active species may be a key to understand the high ORR activity of Cu-Hdatrz or to design bio-inspired catalysts based on multinuclear copper complexes.

Figure 1. Molecular structure of Cu-Hdatrz.

## Introduction

Nanofabrication of functional molecular layers has recently attracted much interest in various research fields such as molecular electronics. Although self-assembled monolayers (SAMs) of thiol molecules have been extensively studied due to their simple fabrication process, it is still difficult to form two-dimensional nano-structures. Recently, we fabricated monolayer nanodots of methylbenzenethiols on Au(111) surfaces using Au nanoparticle (AuNP) assisted electrochemical reductive desorption of thiols. In this work, we constructed monolayer nanodots of ferrocene-terminated alkanethiols on Au(111) electrodes. The electrochemical behavior of the ferrocenethiols was examined by cyclic voltammogram (CV).

## Experimental

A mixed SAM of 11-ferrocenyl-1-undecanethiols (FcC11SH) and decanethiols (C10SH) was formed by immersing of an Au(111) electrode in ethanol solution of the thiols at 1 mM total thiol concentration. For monolayer nanodots, a uniform monolayer was firstly prepared using ethanol solution of 1 mM FcC11SH. AuNPs were then deposited on top of the SAM by soaking the SAM-covered electrode in colloidal gold solution. The electrochemical potential was applied to the electrode in KOH solution, at which SAMs were reductively desorbed from the Au(111) surface but remain intact within AuNP-@Au(111) gaps. Finally, C6SH were introduced in the nanodot-formed electrode in a similar manner.

## Results and Discussions

Figures (a) and (b) show schematic illustrations of the mixed SAM and monolayer nanodots with FcC11SH. When the surface density of ferrocene is low enough in the mixed SAM, each ferrocene is expected to be isolated from others. This is indeed supported by CV of the SAM in the red line of Fig. (c); a pair of sharp redox peaks at +0.25 V vs. Ag/AgCl is similar to that of free ferrocene molecules. On the other hand, the CV of the nanodots exhibited an additional redox peak at around +0.40 V, as shown in the blue line of Fig. (c). It is known that the highly ordered SAM of ferrocenethiols shows positively shifted redox peaks because the interaction between ferrocene moiety and counter anions is sterically hindered. Therefore, the observed electrochemical behavior strongly suggests that FcC11SH were indeed packed with island forms in the monolayer.

Figure. Schematic illustrations of (a) the mixed SAM and (b) monolayer nanodots. (c) CVs of the mixed SAM (red line) and monolayer nanodots (blue line).

# X-ray spectroscopic analyses of electronic states on quinone-based cathode materials for Li-ion batteries

kitada@mail.tagen.tohoku.ac.jp

There is now an increasing demand of secondary batteries with a low cost and high energy density for large-scaled applications such as electric vehicles and peak load leveling installations. Recently, redox-active organic materials are attracting many attentions as an alternative to conventional active materials, LiCoO<sub>2</sub>, LiFePO<sub>4</sub> and LiNiO<sub>2</sub>, due to their advantages such as low costs, low environmental loads and flexibility of molecular design<sup>[1]</sup>. Quinone-based molecules have been studied as promising candidates for cathode materials, since a quinone skeleton shows a multi-electron redox reaction<sup>[2]</sup>. It is essential for a proper molecular design to understand a relation between electronic states and electrochemical characteristics. Spectroscopic analysis is a powerful tool for observing electronic states of organic active materials, whereas there are few reports. In this study, electronic states of quinone-based active materials in electrochemically discharged states were investigated by X-ray photoelectron spectroscopy (XPS) and X-ray absorption spectroscopy (XAS).

We used 9,10-anthraquinone (AQ), 1-chloro-9,10-anthraquinone (1-ClAQ), 1,5-dichloro-9,10-anthraquinone (1,5-diClAQ), 5,12-naphthacenequinone (NCQ) and 6,13-pentacenequinone (PCQ) as cathode materials. Figure 1 shows a half-reaction of AQ. Electrochemically reduced quinone compounds (reduced-quinone lithium compounds) were obtained by galvanostatic discharge tests at 0.2C until -2.0V vs Ag<sup>+</sup>/Ag by a three electrode beaker cell, followed by drying in a vacuum. XAS measurements were carried out at the soft-X-ray beamline BL-7A at Photon Factory in High Energy Accelerator Research Organization.

Figure 2 shows XAS spectrum of AQ pristine (AQ) and electrochemically reduced AQ Li compound (AQ-Li). Peaks at 285.0 and 287.0 eV and a peak at 286.0 eV appear only in AQ and AQ-Li, respectively. These results indicate that electronic states of not only the C-O bonding but the aromatic ring in a quinone skeleton dynamically change between the oxidized and reduced states.

In the presentation, detailed analyses of ab initio calculation, FT-IR, XPS and XAS for 1-ClAQ, 1,5-diClAQ, NCQ and PCQ will be reported with a comparison discussion.

# On the origin of the greatly different kinetics of the hydrogen electrode reactions on Pt in acid and alkaline media

Junxiang Chen, Shengli Chen\*

Department of Chemistry, Wuhan University, Wuhan, China  
slchen@whu.edu.cn

The hydrogen electrode reactions, including the hydrogen evolution and oxidation reactions (HER and HOR), have long served as the model reactions in electrochemical kinetics. Besides, they are key reactions in hydrogen energy technologies. Pt is so far the best metal electrocatalysts for the HER and HOR. Although having been extensively and intensively studied for decades, there remain numerous questions standing in the electrocatalysis of HER and HOR on Pt-based materials. One question that has received considerable recent attentions, due to the increasing interest in alkaline fuel cells, is why the HER and HOR exhibit much slower kinetics on Pt in alkaline media than in acidic media, although in both conditions Pt is the best metal electrocatalyst.[1] The answer to this question should help designing the hydrogen electrode catalysts for alkaline fuel cells and water electrolysis. In this study, we investigate the pH effect on the hydrogen electrode kinetics on Pt(111) surface by combining the density functional theory (DFT) calculation and micro kinetic model analysis. The results lead to two main conclusions.

**1. The hydrogen electrode reactions on Pt should follow the Volmer-Heyrovsky instead of Volmer-Tafel mechanism, with the Heyrovsky reaction being the rate-determining step (*rds*).** Considering the highly reversible hydrogen adsorption and desorption behaviors indicated in the cyclic voltammogram (CVs) in both acid and alkaline media, the Volmer reaction ( $\text{H}^+ + \text{e}^- + * \leftrightarrow \text{H}^*$  and/or  $\text{H}_2\text{O} + \text{e}^- + * \leftrightarrow \text{H}^* + \text{OH}^-$ ) can be approximately considered being in equilibrium. Therefore, it should not be the *rds* regardless of pH. For the Tafel and Heyrovsky reaction, the exchange current density  $j_0$  are derived as

$$j_0^{\text{Tafel}} = 2Fk_0^{\text{T}}\theta_{\text{H}^*}(1-\theta_{\text{H}^*})(c_{\text{H}_2})^{0.5} \quad (1)$$

$$j_0^{\text{Heyrovsky}} = 2Fk_0^{\text{H}}\theta_{\text{H}^*}(1-\theta_{\text{H}^*})(c_{\text{H}^+}c_{\text{H}_2})^{0.5} \quad (2)$$

where  $k_0^{\text{T}}$  and  $k_0^{\text{H}}$  refer to the standard rate constants of the Tafel and Heyrovsky reactions;  $\theta_{\text{H}^*}$  is the coverage of  $\text{H}^*$  at the equilibrium electrode potential;  $c_{\text{H}^+}$  and  $c_{\text{H}_2}$  are the concentrations of  $\text{H}^+$  and  $\text{H}_2$  in the solution. For the Tafel reaction, pH may alter the  $j_0$  mainly by changing the  $\theta_{\text{H}^*}$  (eq. 1). Our DFT calculation results show that the  $\theta_{\text{H}^*}$  in acid solution (pH=1) is about 1.3 times lower than that in alkaline solution (pH=13), which, according to eq. 1, would predict a larger  $j_0$  in the alkaline solution. This obviously contradicts to the much lower  $j_0$  in alkaline media observed in experiments [1]. As indicated by eq.2, the  $j_0$  for the Heyrovsky reaction is affected by the  $\theta_{\text{H}^*}$  and  $c_{\text{H}^+}$ . Therefore, large pH effect could occur if the Heyrovsky reaction is the *rds*.

**2. The Heyrovsky reaction proceeds in different ways in acid and alkaline media.** The Heyrovsky reaction may proceed in two ways, namely,  $\text{H}^* + \text{H}^+ + \text{e}^- \leftrightarrow \text{H}_2 + *$  (H1) and  $\text{H}^* + \text{H}_2\text{O} + \text{e}^- \leftrightarrow \text{H}_2 + \text{OH}^- + *$  (H2) respectively. The two types of reaction paths should have different kinetics due to that different proton donors and acceptors are involved. By using the DFT-calculated  $\theta_{\text{H}^*}$  and the values of  $c_{\text{H}^+}$ , eq. 2 predicts  $j_0$  values that differ ca. 7 order of magnitude in acid (pH=1) and alkaline (pH=13) if the same  $k_0^{\text{H}}$  is used, which is also against that observed in experiments. Therefore, we think that the Heyrovsky reaction proceeds mainly through H1 in acid solution, while the H2 is the major reaction path in alkaline solution. By fitting the experimental polarization curves for the HER and HOR obtained in different media, the standard reaction constants for the Heyrovsky reactions in solutions of pH=1 and pH=13 are found to be  $1 \times 10^{-4} \text{ s}^{-1}$  and  $4 \times 10^{-7} \text{ s}^{-1}$ , respectively.

# In Situ DRIFTS Analysis of SEI formation over Cathodes at Elevated Temperature

Minbale Admas Teshager, Shawn D. Lin\*, Bing Joe Hwang\* and Yaw-Terng Chern  
Department of Chemical Engineering, National Taiwan University of Science and Technology, Taipei,  
Taiwan 106, R.O.C.

\*E-mail: [sdlin@mail.ntust.edu.tw](mailto:sdlin@mail.ntust.edu.tw) (S. D. Lin) and [bjh@mail.ntust.edu.tw](mailto:bjh@mail.ntust.edu.tw) (B. J. Hwang)

The thermal and electrochemical instability of conventional  $\text{LiPF}_6$ -organocarbonate electrolytes hinder the integration of large-scale lithium ion batteries (LIBs) for high powered electric vehicles (EVs), hybrid electric vehicles (HEVs), plug-in hybrid electric vehicles (PHEVs) and smart grids [1]. Its thermal decomposition has been considered as the main challenge at moderately elevated temperature (60-85°C) and result in catastrophic failure of the battery. Wilken et al. [2] and Yang et al. [3] reported the thermal decomposition of  $\text{LiPF}_6$ -based electrolyte using ex situ techniques such as NMR, GC-MS, and on-line-TGA-FTIR. They found fluorinated organic and inorganic species as decomposition products. However, the decomposition products of electrolyte at elevated temperature and solid electrolyte interface (SEI) formation in the real battery system is still a debating issue, due to the lack of direct evidence from in-situ analysis. In situ diffuse reflectance infrared Fourier-transformed spectroscopy (DRIFTS) is proved a convenient technique for SEI analysis[4]and will be used in this study at elevated temperature.

Another important issue is electrochemical stability of electrolyte, for which new Li-salt electrolyte with large redox window is persistently required. Very recently Chern et al. [5] reported, a new cyano-substituted benzimidazole derivative Li-salt,  $(\text{Li}[5\text{-CNTFBI}(\text{BF}_3)_2])$ , for high temperature and high potential application of LIBs. However, complicated interaction occurs between Li salt, solvent, additive, and electrode surface within a cell wherein the change of only one electrolyte component would require reconsideration of SEI chemistries of the electrodes. Perhaps therefore, studies of new electrolytes are few in number and in general new Li-salts are hardly investigated and developed in LIBs.

Here, we report in-situ DRIFTS analysis at elevated temperature (65°C) during electrochemical cycling using a commercial electrolyte ( $\text{LiPF}_6/\text{EC}+\text{DEC}$ ) and the new electrolyte of cyano-benzimidazole derivative Li-salt ( $\text{Li}[5\text{-CNTFBI}(\text{BF}_3)_2]/\text{EC}+\text{DEC}$ ) over two cathode materials (Li-rich LLNMO and commercial  $\text{LiCoO}_2$ ). Fig.1 illustrates the DRIFTS difference spectra using the commercial electrolyte,  $\text{LiPF}_6/\text{EC}+\text{DEC}$  (a) and  $\text{Li}[5\text{-CNTFBI}(\text{BF}_3)_2]/\text{EC}+\text{DEC}$  (b) over Li-rich LLNMO cathode. In the case of  $\text{LiPF}_6$  system (Fig.1a), absorbance bands indicating decomposition product of  $\text{LiPF}_6$  along with EC adsorption were detected at a lower potential of 3.8 V than that at room temperature [6]. With the new electrolyte (Fig.1b), there is no indication of decomposition product other than EC adsorption at below 4.4V, suggesting that the new electrolyte is promising for high temperature application of LIBs. SEI species observed above the mentioned onset potential were somewhat different for the two electrolyte systems. The identified species and their possible formation mechanism will be discussed and compared to that observed at room temperature and over commercial  $\text{LiCoO}_2$  cathode.

**Acknowledgement:** We are grateful to Ministry of Economic Affairs of Taiwan, ROC (103-EC-17-A-08-S1-183) for the financial support.

**Fig.1** DRIFTS difference spectra of using  $\text{LiPF}_6/\text{EC}+\text{DEC}$  (a) and  $\text{Li}[5\text{-CNTFBI}(\text{BF}_3)_2]/\text{EC}+\text{DEC}$  (b) electrolyte over LLNMO during electrochemical charging at elevated temperature (65°C).

# Optical Force Applied to Molecules at Nanogap of Metal Nanodimer

Yumi Wakisaka, Mai Takase, Hiro Minamimoto, Satoshi Yasuda, Kei Murakoshi

*Department of Chemistry, Hokkaido University*

*Sapporo, Hokkaido, 060-0810, Japan*

*kei@sci.hokudai.ac.jp*

Optical manipulation of molecules at room temperature is a key for sophisticated nanotechnology in future. We have developed the system to segregate molecules using the steep gradient of the chemical potential at metal nanogap less than 100 nm in width [1]. Our results demonstrated that the force of <fN applied to a single molecule is enough to control molecular 2D diffusion at room temperature [2]. Several innovative findings on optical manipulation for molecules are available both on experiment and theory [3]. Optical trapping of molecule at room temperature, however, has not been achieved yet. Recently, it has been shown that highly localized anisotropic electromagnetic field generated by plasmon resonance of metal nanodimer emerge very characteristic phenomena of the alternation of selection rule at the optical excitation [4], and the change in Raman scattering due to strong coupling between plasmons and molecule excitons [5]. Such huge gradient of the field could be used to generate optical force in the order of sub-pN for controlling molecule motions [3]. In the present work, possibility of the molecule trapping at the gap of metal nanodimer is discussed based on the observation of the signal evolution of surface-enhanced Raman scattering reflecting the increment of the number of molecules in the plasmon field. The orientation of molecules adsorbed on the surface of metal is controlled by electrochemical potential to estimate the effect of the anisotropy of the electromagnetic field to polarize molecules.

<sup>b</sup>Chemical Engineering Department, ISEL, R. Conselheiro Emídio Navarro, 1959-007 Lisboa, Portugal.  
[pombeiro@tecnico.ulisboa.pt](mailto:pombeiro@tecnico.ulisboa.pt)

Three new mononuclear Fe(III) complexes with ligands derived from 3-amino-2-pyrazinecarboxylic acid, [H(EtOH)][FeCl<sub>2</sub>(L)<sub>2</sub>] (**1**) [L = 3-amino-2-pyrazinecarboxylate], [H<sub>2</sub>bipy]<sub>1/2</sub>[FeCl<sub>2</sub>(L)<sub>2</sub>].DMF (**2**) and [FeCl<sub>2</sub>(L)(2,2'-bipy)] (**3**) (Figure 1) were prepared and characterized.

Figure 1

The electrochemical behaviours of complexes **1-3**, as well as of 3-amino-2-pyrazinecarboxylic acid (HL), doubly protonated 4,4'-bipyridine [(H<sub>2</sub>bipy)Cl<sub>2</sub>] and 2,2'-bipyridine, were investigated by cyclic voltammetry (CV) and controlled potential electrolysis (CPE), at a platinum working electrode at room temperature in a 0.2 M [<sup>n</sup>Bu<sub>4</sub>N][BF<sub>4</sub>]/NCMe solution.

Complexes **1-3** exhibit a first single-electron (as measured by CPE) reversible cathodic wave at *ca.* 0.06 V vs. SCE, assigned to the Fe(III) to Fe(II) reduction (wave I<sup>red</sup>). A second irreversible cathodic wave (II<sup>red</sup>) in the -0.62 to -1.12 V vs. SCE range is also observed, which involves the L<sup>-</sup> ligand. A typical cyclic voltammogram is exemplified for **3** in Figure 2.

Figure 2 - Cyclic voltammogram, initiated by the cathodic sweep, of **3** in a 0.2 M [<sup>n</sup>Bu<sub>4</sub>N][BF<sub>4</sub>]/NCMe solution, at a Pt disc working electrode (*d* = 0.5 mm), run at a scan rate of 200 mVs<sup>-1</sup>. \* [Fe(η<sup>5</sup>-C<sub>5</sub>H<sub>5</sub>)<sub>2</sub>]<sup>0/+</sup>.

The electrochemical study provided a valuable tool to establish the structures of complexes **1** and **2**.

The values of the Fe<sup>II/III</sup> redox potential of our complexes also allowed to estimate, for the first time, the value of the Lever *E<sub>L</sub>* electrochemical ligand parameter for the 3-amino-2-pyrazinecarboxylate ligand, on the basis of the Lever linear relationship (eq. 1).

$$E = S_M (\Sigma E_L) + I_M \quad (1)$$

# In-Situ Monitoring the Electrocatalytic Reaction Processes at Platinum Single Crystal Electrode Using SHINERS

Jin-Chao Dong, Du-Hong Chen, Yue Li, Jin-Hui Meng, Yang Zhao, Chao-Yu Li, Jian-Feng Li\*  
*College of Chemistry and Chemical Engineering, Xiamen University, Xiamen 361005, China*  
*E-mail: Li@xmu.edu.cn*

Raman spectroscopy, as a vibrational spectroscopy technique, can provide detail structural information about the probed molecules, however, the signal intensity is too weak. The discovery of surface-enhanced Raman scattering (SERS) paved way for sensitive detection of target analytes even down to single molecule level, but the applications of the SERS are limited by a lack of substrate generality and its high surface selective performance. Since our group invented “shell isolated nanoparticle-enhanced Raman spectroscopy” (SHINERS) in 2010, it received more and more attention by many research groups. SHINERS entails metal nanoparticles with thin inert silica shell and the inner Au NPs are treated as “signal amplifiers” which can enhance the Raman signal of target molecules due to its strong electromagnetic field. The ultrathin silica shells can effectively isolate the “signal amplifiers” from the ensemble, and also avoid aggregation of nanoparticles. The SHINERS technique offsets the long-standing limitations of SERS such as substrate and morphology generality to a certain extent. It has been widely accepted by different fields such as electrochemistry, surface science, analytical science, and especially applied at atomically flat single crystal electrode surfaces.

From the perspective of catalytic materials and energy fields, the platinum and platinum alloy owned the best catalyst activity in fuel cells, so the electrocatalytic reactions, which using platinum as working electrodes, get lots of concerns. Currently, there are many studies on the electrochemical properties of the platinum electrodes, however, in-situ monitoring the electrocatalytic reaction processes at single crystal platinum electrodes using Raman spectroscopy has not been reported. We employ in-situ EC-SHINERS technique to in-situ monitor the electrocatalytic processes of CO, methanol, formic acid oxidation, and oxygen reduction at Pt single crystal electrodes and systematically evaluate the influence of different factors, such as crystallographic orientations, anions and pH, during reaction processes.

## 1. Introduction

It is shown in our previous papers that the Au deposition occurs mainly at atomic steps resulting the layer-by-layer growth at potentials near the onset of cathodic currents over the entire area (ca.  $100 \times 100 \mu\text{m}^2$ ). New small islands with a monatomic height were also observed on atomically flat terraces during the deposition. These islands expanded in the lateral direction, resulting the formation of new layers. A laser confocal microscope combined with a differential interference contrast microscope (LCM-DIM) used to observe the electrochemical dynamic processes.

LCM-DIM provides direct images of dynamics in the electrochemical deposition of Au with an atomic layer resolution [1,2]. It is also demonstrated that LCM-DIM can be applied for other reactions such as upd processes of Ag, Cu on Au electrodes and Si(100)[4]. More recently, it has been found that the intercalation reaction of Li ions [3] into layered material such as transition metal chalcogenides can be imaged by our new technique. Here, we show unique capability of the new optical microscopy.

## 2. Experiment

The apparatus of our LCM-DIM was constructed and improved using an optical system (FV300, Olympus Optical Co. Ltd.) with a super-luminescent diode (Amonics Ltd., Model ASLD68-050-G-FA:680 nm) to eliminate interference fringes. We usually used a mode with data points ( $512 \times 512$  points), in which the speed of 4 frames/s can be achieved. It was necessary to prepare ultra-flat surfaces with terrace widths greater than several micrometers, because the lateral resolution of the LCM-DIM method was limited in the range of 0.2–0.3  $\mu\text{m}$  by the wavelength of the monitoring light as in the conventional optical microscopy.  $\text{MoS}_2$  surface was prepared by cleaving method. Ionic liquid used as electrolyte solution (EMI-FSI) containing 0.32 mol/kg lithium (LiTFSI). Lithium foil used as reference and counter electrode.

## 3. Result and Discussion

It has been shown that the Au deposition occurs mainly at atomic steps resulting the layer-by-layer growth at potentials near the onset of cathodic currents over the entire area (ca.  $100 \times 100 \mu\text{m}^2$ ). New small islands with a monatomic height were also observed on atomically flat terraces during the deposition. These islands expanded in the lateral direction, resulting the formation of new layers. LCM-DIM provides direct images of dynamic growth modes in the electrochemical deposition of Au with an atomic layer resolution [2].

Recently, it has been demonstrated for the first time that in situ imaging of the dynamic processes of Li ions intercalation reactions into  $\text{MoS}_2$  single crystal electrodes with an atomic layer resolution is now possible in an ionic liquid, using LCM-DIM as shown in Fig.1(a-c). It can be concluded that the intercalation reaction occurs in the two phases forming undoped and doped domains. Newly formed intercalated Li ions, push away to all previously intercalated all Li ions to the inner part of undoped  $\text{MoS}_2$  phase as illustrated in Fig.1(d)

Figure1. The Li intercalation and de-intercalation(a-c) process into  $\text{MoS}_2$  and (d) schematic illustration of intercalation process.

# The Redox Behaviour of Graphene Oxide: A Spectroelectrochemical Study

Martin Pfaffeneder-Kmen, Günter Trettenhahn  
*Department of Physical Chemistry, University of Vienna*  
*Währinger Straße 42, A-1090, Vienna*  
*guenter.trettenhahn@univie.ac.at*

Since 2004, when Novoselov and Geim published their groundbreaking work about the preparation and characterization of graphene,[1] great interest in this material developed. Very soon there was the demand for new synthesis methods, because the method, which was described in this paper, was only suitable for research. Starting with this motivation, graphene oxide (GO) was proposed to be a possible precursor to graphene.[2] GO is now known since more than 150 years as graphitic acid,[3] but it is state-of-the-art and many possible applications have been published in the past few years.[4,5]

The exact structure of GO is still under discussion, but the Lerf-Klinowski model is generally accepted.[6] It says that the single sheets in graphite are decorated with the most different oxygen containing groups, mostly alcohols, epoxides and at the sheet edges carboxylic acid groups. The structure is completely non-ordered and a recent electrochemical study showed, that the final GO product depends even on the synthesis method.[7] The oxygen containing groups decrease the hydrophobicity of the sheets and make the dispersion of GO and the exfoliation to single nanosheets in water (depending on the pH)[8] and other solvents possible.[9] The electrochemical reduction [10] is favored, because, structural defects can be healed [4] and aggressive reductants can be avoided. In the literature it was published as green method.[11]

Therefore the reduction mechanism and the structure of the final product are of great interest. In this study the GO/electrolyte interface was investigated by in-situ ATR FTIR spectroscopy. The very fundamental reduction behavior of GO is described, as well as the possible oxidation of the reduced form. Although there are no reversible redox processes, the reduced form can be electrochemically re-oxidized. This work describes the formation and degeneration of oxygen containing groups during cathodic reduction. In situ FTIR data obtained in aqueous and D<sub>2</sub>O solutions elucidated the reduction reaction of GO.

## Potentiostatic pulse technique to investigate the hydrogen diffusion and trapping into subsurface of nickel single crystal (100)

X. Feaugas, C. Lekbir, E. Conforto, J. Creus, R. Sabot

*LaSIE UMR 7356 CNRS, Université de la Rochelle, Av. Michel Crépeau, 17042 La Rochelle, France.*

*Email addresses : [xavier.feaugas@univ-lr.fr](mailto:xavier.feaugas@univ-lr.fr)*

A potentiostatic double-step technique was applied to unstrained (US), strained with suppression of strain bands (SWB) and strained (S) Ni (100) single crystal surfaces in sulphuric acid medium to characterize hydrogen diffusion and trapping in relation with the different effects of plastic strain [1]. In these potentiostatic pulse experiments, the hydrogen atoms are generated at a constant cathodic potential  $E_C$  for a time  $t_C$  in the range of 2 to 1200s. During this charging period a proportion of the hydrogen atoms diffuse into the electrode interior. At the end of the charging period the potential is stepped to a more positive value  $E_0$  (a few millivolts negative of its corrosion potential  $E_C$ ) resulting in an anodic current transient and charge  $q_A$  associated with the re-oxidation of hydrogen atoms. Diffusion and trapping parameters:  $\langle F.C_S.(D/\pi)^{1/2} \rangle$  and  $\langle k_T \rangle$  are determined by fitting the experimental current transients to the theoretical solution of an appropriate model [2]. For US Ni (100) surfaces, the effect of trapping on the diffusion of hydrogen is not taken into account and show that the residual dislocation densities present in metal is negligible with respect to the trapping. Two domains can be distinguished, that of the subsurface and that of the bulk of the sample. For all mechanical states studied we observe that the diffusion coefficient near the surface (subsurface) seems to be much higher than that obtained in the bulk of the metal, and that the density of trapping sites decrease around the surface. According to thermodynamic framework the origin of both results is analysed and possible implication on hydrogen embrittlement is discussed.

# Imaging of electrocatalytical activities of mixed transition metal oxides for oxygen reduction reaction with scanning electrochemical microscopy

Fei Li, Li Ma, Han Zhou, Shuli Xin, Chunhui Xiao and Shujiang Ding

Department of Chemistry, School of Science, Xi'an Jiaotong University, Xi'an 710049, P.R. China  
feili@mail.xjtu.edu.cn

Looking for cheap and commercially available materials to replace the precious and nondurable Pt catalysts to facilitate the sluggish oxygen reduction reaction (ORR) is a key issue in fuel cells. In recent years, various alternative catalysts based on non-precious metals have been developed, in which the mixed valence oxides of transition metals have attracted much attention due to their considerable advantages of low cost, environmental friendliness, prominent ORR activity and stability. In this work, the  $\text{ZnCo}_2\text{O}_4$  nanosheets@CNT ( $\text{ZnCo}_2\text{O}_4$  NSs@CNT) and the  $\text{Co}_3\text{O}_4$  nanosheets@CNT ( $\text{Co}_3\text{O}_4$  NSs@CNT) composites with hierarchical and sheet-like structure were successfully synthesized on the CNT covered with sulfonated polystyrene layer by virtue of sulfonated gel medium. Their catalytic activities for ORR measured by cyclic voltammetry show that the  $\text{ZnCo}_2\text{O}_4$  NSs@CNT composite exhibits the highest ORR catalytic activity compared with  $\text{ZnCo}_2\text{O}_4$  NSs, CNT alone, the physically mixed  $\text{ZnCo}_2\text{O}_4$  and CNT and the  $\text{Co}_3\text{O}_4$  NSs@CNT, which could contribute to the unique “cable” structure of  $\text{ZnCo}_2\text{O}_4$  NSs@CNT providing large surface area and great electron conductivity for catalyzing oxygen reduction, and the synergetic effect between  $\text{Zn}^{2+}$  and  $\text{Co}^{3+}$ . And the presence of CNT as support could provide sufficient electric conductivity for the rapid electron transfer and form an efficient and well-connected structure with  $\text{ZnCo}_2\text{O}_4$ . The simultaneous investigation and comparison of the catalytic activities of these catalysts at a same GCE in one single experiment were also achieved by scanning electrochemical microscopy (SECM). The obtained SECM results agree well with the CV results and additionally provide the differences in the local catalytic activities of these catalysts at different sample potentials. The better catalytic performance of  $\text{ZnCo}_2\text{O}_4$  nanosheets@CNT than that of the cobalt-based oxides ( $\text{Co}_3\text{O}_4$ ) shows promising as a new non-Pt, mixed transition metal oxides ORR catalyst for future fuel cell applications.

# Noise and ac impedance analysis of ion transfer kinetics at the micro liquid/liquid interface

Vladimír Mareček, Oksana Josypčuk, Karel Holub  
J. Heyrovský Institute of Physical Chemistry of the CAS, v.v.i.  
Dolejšková 2155/3, 182 23 Prague 8, Czech Republic  
vladimir.marecek@jh-inst.cas.cz

Fluctuation analysis was utilized to determine the TEA ion transfer kinetics across the water/1,2-dichloroethane interface. The obtained data were compared with those derived from electrochemical impedance spectroscopy experiments using the same electrolytic cell. A two electrode cell with the liquid/liquid interface supported at the tip of a silanised microcapillary with an open circuit potential of 0 V was used throughout:

Ag/AgCl/x mM LiCl + 0.5 mM TEACl(w)/x mM TBATPB + 0.5 mM TEADCC(o)/x mM LiCl + 0.5 mM TEACl(w)/AgCl/Ag (1)

where  $x = 10$  or  $20$ . The capillary with orifice diameter of approximately  $18\ \mu\text{m}$  was prepared similarly as previously reported [1]. Home-made low noise - high impedance input preamplifier equipped with a high-pass filter was constructed using operational amplifiers INA116 and OPA 2227 (Texas Instruments). The preamplifier output was connected to the Dynamic Signal Analyzer HP 35665A (Hewlett Packard). FFT data were obtained in three frequency spans 0-1.6; 0-12.8 and 0-102.4 kHz, each with the 800 lines resolution. The square of the noise mean amplitude  $V(f)$  is related to the real part of impedance  $Z_r$  by the Nyquist formula  $V(f)^2 = 4kTZ_r\Delta f$ .

The noise analysis data of the cell (1) for  $x = 10$  are shown in Fig. 1. The curve *a* represents a fit to the noise data measured for the cell only filled with the aqueous phase, i.e. without a liquid/liquid interface. The electrical equivalent circuit used in a fitting procedure is composed of a parallel combination of the cell resistance  $R$  and capacitance  $C$ . At low frequencies below 3 kHz, the value of  $Z_r$  is constant and represents resistance of the cell  $R = 1.7\ \text{M}\Omega$ . The  $Z_r$  decrease at high frequencies is caused by a parallel capacitance  $C$  which amounts to 10 pF. It comprises the input capacitance of the preamplifier  $C_i = 5\ \text{pF}$  and a stray capacitance of the cell  $C_s$ .

The thick full line in Fig. 1 represents a fit to the noise data *b* measured in the presence of a liquid/liquid interface. The noise data were fitted using a real part of the impedance  $Z_r$  of the equivalent circuit shown in the inset of Fig. 1. In contrast to the line *a*, the real part of the impedance is not constant at low frequencies, but increases with decreasing the frequency below 3 kHz. The impedance decrease at high frequencies, similar to line *a*, is analogously due to the parallel capacitance  $C$ , amounting in this case to 5.4 pF only.

Ac impedance of the cell was determined before and after the noise measurement. The purpose

of these ac impedance measurements was to check the electrolytic cell stability and to compare the ac impedance data with those derived from the noise measurement. The ac impedance data obtained before and after the noise measurement are almost identical, which proves stability of the electrolytic cell.

Kinetic parameters derived from the ac impedance and the noise data are in a very good agreement. The average rate constant value  $k_s = 0.37\ \text{cm s}^{-1}$  corresponds to the value obtained previously [1] with the ac impedance spectroscopy technique. It is therefore evident that the ac impedance technique utilizing a small amplitude perturbation signal is comparable with a noise analysis and the both methods provide reasonable data on

the ion transfer kinetics. Application of a method employing a small perturbation signal prevents polarization of the inner capillary surface by current flowing through the cell [2]. The induced polarization of the capillary can affect ion concentration at the interface due to electroosmosis and thus make the kinetics data evaluation difficult or erroneous.

<sup>a</sup>*Yekaterinburg, 620990, Russia,*

<sup>b</sup>*Yekaterinburg, 620002, Russia*

*o.v.limanovskaia@urfu.ru*

The non-stationary behavior of platinum anode in the KF–NaF–AlF<sub>3</sub>–Al<sub>2</sub>O<sub>3</sub> melt has been studied by means of voltammetry and chronopotentiometry in previously our work [1]. The pre-peak near the oxygen oxidation peak is found to be on the almost all experimental cyclic voltammetry curves. Although it was suggested that the nature of the process corresponding with that pre-peak has non diffusion nature, the mechanism of this process is still not clear. This work presents the mathematical model of this process and comparing of calculation and experimental results.

It was proposed [1] that the pre-peak caused by dynamical forming and decomposition of platinum oxide compound on the platinum surface. Therefore the following reactions may be assumed:

The partial currents of these processes may be written as follow:

$$i_1 = i_{01} \cdot \left\{ \frac{X}{X_0} \cdot \frac{1-\Theta}{1-\Theta_0} \cdot e^{\frac{2\alpha NuF}{RT}} - \frac{Y}{Y_0} \cdot \frac{\Theta}{\Theta_0} \cdot e^{\frac{-2(1-\alpha)NuF}{RT}} \right\} \quad (3)$$

$$i_2 = i_{02} \cdot \left\{ \frac{\Theta}{\Theta_0} - \left( \frac{C_{O_2}}{C_{O_2}^0} \right)^{\frac{1}{2}} \frac{1-\Theta}{1-\Theta_0} \right\} \quad (4),$$

where  $i_{01}$ ,  $i_{03}$  – exchange current of (1) and (2),  $X$ ,  $X_0$  – local and initial concentration of  $Al_2O_2F_4^{2-}$  ions,  $Y$ ,  $Y_0$  – local and initial concentration of  $Al_2OF_6^{2-}$  ions,  $\theta$ ,  $\theta_0$  – local and initial value of surface filling degree,  $Nu$  – potential,  $F$ – Faraday,  $R$ – Gas constant,  $T$  – temperature,  $C_{O_2}$ ,  $C_{O_2}^0$  – local and initial concentration of oxygen.

The expressions (3) and (4) were used as base for modeling calculations with follow assumption. As far the pre-peak has non-diffusion nature changing of concentration of  $Al_2O_2F_4^{2-}$  and  $Al_2OF_6^{2-}$  ions have been ignored. The changing of oxygen concentration has been ignored too because oxygen concentration so large that it's changing is negligible. Figure 1 shows the results of modeling calculations.

Fig. 1 Comparing modelling and experimental results

As seen in Figure 1, the modeling and experimental results appeared to be considerable matching.

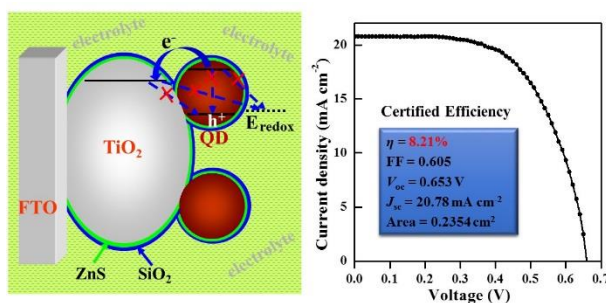

# Ligand Induced Self-Assembly for High Efficiency Quantum Dot Sensitized Cells

Xinhua Zhong

School of Chemistry and Molecular Engineering, East China University of Science and Technology  
Shanghai 200237, China  
e-mail: zhongxh@ecust.edu.cn

A higher surface coverage of QD sensitizers on the oxide substrate is a “must” to improve the efficiencies of quantum dot sensitized solar cells (QDSCs). Due to the big size and lack of anchoring site on colloidal QD surface, the deposition of colloidal QD on  $\text{TiO}_2$  film electrode has been a bottleneck in the construction of high efficiency QDSCs. A ligand-induced self-assembly approach, wherein QDs capped with bifunctional linker ligands such as mercaptopropionic acid (MPA) are immobilized on  $\text{TiO}_2$  prompted by the affinity between carboxyl group and  $\text{TiO}_2$ , has been developed to achieve fast, uniform, and dense deposition of colloidal QD on  $\text{TiO}_2$  electrode.<sup>[1-3]</sup> Meanwhile, alloyed and type-II core/shell structured QD sensitizers with features of wide absorption range and high conduction band edge have been designed and prepared.<sup>[4-7]</sup> Furthermore, the potential charge recombination inside QD, and at  $\text{TiO}_2/\text{QD}/\text{electrolyte}$  interfaces is substantially suppressed with the use of a double inorganic coating treatment, consisting of a novel optimized  $4\text{ZnS}/\text{SiO}_2$  recipe onto QD sensitized  $\text{TiO}_2$  electrodes.<sup>[7,8]</sup> With the combination of high-quality QD sensitizers, effective deposition technique, and suppressed charge recombination, the power conversion efficiency (PCE) of QDSCs under simulated AM 1.5, full 1 sun illumination has been improved steadily from the level of 4-5% to a certified value of 9.0%.<sup>[1-9]</sup> We believe that through optimizing the electrolyte and counter electrode, the PCE of QDSCs will break through 10% (the threshold for commercial applications) in the near future.

**Figure.** (left) Schematic illustration of charge recombination suppressed by the ZnS/SiO<sub>2</sub> energetic barrier layers; (right) Certified efficiency of 8.21% based on CdSeTe QDSC.

## Methodologies for 20% Efficient Perovskite Solar Cells

Nam-Gyu Park

*School of Chemical Engineering and Department of Energy Science*

*Sungkyunkwan University, Suwon 440-746, Korea*

*npark@skku.edu*

Since the groundbreaking report on long-term durable solid-state perovskite solar cell based on organolead halide in 2012, perovskite solar cell has been considered as a promising and potential alternative to silicon or CIGS solar cells due to low-cost and superb performance. In this talk, methodologies will be presented to achieve perovskite solar cells with power conversion efficiency approaching 20%. Morphology of  $\text{CH}_3\text{NH}_3\text{PbI}_3$  (MAPbI<sub>3</sub>) perovskite can be controlled from 3-dimensional (3D) to 1-dimensional (1D) nanostructures. 3D nanocuboids were prepared by two-step spin-coating method, where cuboid size was controlled by engineering solution concentration. Light harvesting efficiency, hole mobility rate and charge extraction were significantly dependent on the nanocuboid size. I-V hysteresis was also found to be affected by nanocuboid size. Piezoresponse force microscopic studies confirmed that polarization behavior was strongly affected by the size. 1D nanowire MAPbI<sub>3</sub> was prepared by means of local dissolution of the PbI<sub>2</sub> layer in two-step procedure. Reduction in dimensionality resulted in the hypsochromic shift of both absorption and fluorescence spectra, indicative of more localized exciton states in nanowires. 1D structure showed better lateral conductivity and charge separation at HTM interface than 3D nanocuboid. The power conversion efficiency (PCE) of ~17% and ~15% was achieved from 3D nanocuboids and 1D nanowire, respectively. Processing is critical to have high quality perovskite film, where we have developed reproducible method for 20% efficiency perovskite solar cell via acid-base chemistry. We have also tried to fabricate perovskite solar cell under high relative humidity (RH) outside glove box and attained PCE over 15% from the device prepared at 50% RH. Preliminary results on long-term stability of perovskite solar cell will be also discussed.

# Graphene Oxide Quantum Dots for Photon Energy Conversion

Hsisheng Teng, Te-Fu. Yeh, Liang-Che Chen, Chiao-Yi Teng

*Department of Chemical Engineering and Research Center for Energy Technology and Strategy, National Cheng Kung University, Tainan 70101, Taiwan*  
*hteng@mail.ncku.edu.tw*

Graphene oxide (GO) is a semiconductor that can absorb light to generate electron-hole pairs. The electronic properties of GO can be tuned by varying its size and embedding different functional groups. Doping nitrogen on GO by ammonia treatment can convert p-type GO to an n-type semiconductor. The size effect resulting from quantum confinement also influences the electronic structures of GO. Introducing nitrogen into GO quantum dots has resulted in the coexistence of p- and n-type conductivities in the nitrogen-doped GO quantum dots (NGOQDs) [1]. Under irradiation the photogenerated electron-hole pairs in NGOQDs undergo recombination for photoluminescence or separation for photocatalysis. The function of NGOQDs, as a phosphor or photocatalyst, depends on the defect-state density on the NGOQD surface.

The NGOQDs have a band gap of approximately 2.3 eV. The Pt-deposited NGO-QDs effectively catalyzed H<sub>2</sub> evolution from an aqueous solution containing triethanolamine as a sacrificial electron donor. The quantum yield for H<sub>2</sub> evolution reached a value as high as 13 % under irradiation at 420 nm [2].

Surface-passivated NGOQDs suspended in water or other solvents exhibit strong emission at  $\lambda = 530$  nm, irrespective of the excitation wavelength. Excitation at 470 nm yields a maximum photoluminescence quantum yield. Electron relaxation from the graphene anti-bonding  $\pi$  orbital to the non-bonding oxygen state may be responsible for this emission [3].

# **Impedance Spectroscopic Analysis of Organic-Inorganic Hybrid Perovskite Solar Cell under Different Architectures**

Yu-Tung Yin and Liang-Yih Chen\*

*Department of Chemical Engineering, National Taiwan University of Science and Technology  
No.43, Sec. 4, Keelung Rd., Da'an Dist., Taipei 106, Taiwan  
sampras@mail.ntust.edu.tw*

The organic-inorganic hybrid perovskite ( $\text{CH}_3\text{NH}_3\text{PbI}_3$ ) solar cell with spiro-MeOTAD as a hole transport material (HTM) was investigated via electron impedance spectroscopy (EIS). A model has been established to analysis the frequency response of the perovskite based solar cell, which was derived from the existing models used for the liquid and solid-state dye-sensitized solar cells. The benefit of structure layer existence has been demonstrated in this study. Furthermore, the influence of ferroelectric characteristic of perovskite would also be investigated. On the extraction of fitting EIS parameters, the interfacial electric carriers transport/transfer properties inside perovskite solar cell were studied and correlated with the overall performance of devices. In particular, the features in the EIS responses could be attributed to the ionic and electronic transport properties of the perovskite. The ferroelectric characteristic was strongly correlated with the flatness on the interface of perovskite. The key issues on maintain high performance of perovskite solar cell respect to the EIS analysis were studied.

# Photoelectrochemical characterization of ZnLaTaON based electrodes for water oxidation reaction

<sup>c</sup>Department of Chemistry and Centre for Sustainable Technologies, University of Bath, UK.

The development of an efficient semiconductor photocatalysts for direct conversion of solar energy into chemical energy is one of the most potential approaches to meet the environmental and energy demands.<sup>1</sup> Photoelectrochemical water splitting is promising approach for utilizing solar energy to generate oxygen and hydrogen.<sup>2</sup> It is challenging to develop a semiconductor that has both suitable conduction and valence band for H<sub>2</sub> and O<sub>2</sub> production and narrow band gap (< 3 eV) for visible light absorption. Tantalum oxynitrides (TaON) based materials have that potential for water splitting reaction under visible light reaction.<sup>3</sup> In the present work, we investigated in alkaline medium, the photoelectrochemical properties of Zn<sub>0.5</sub>La<sub>0.5</sub>TaO<sub>1.5</sub>N<sub>1.5</sub>, LaTaON<sub>2</sub> and TaON particles coated onto ITO glass by electrophoretic deposition method.. Also the photoelectrochemical characterizations of Zn<sub>0.5</sub>La<sub>0.5</sub>TaO<sub>1.5</sub>N<sub>1.5</sub> for water oxidation reactions was performed by loading co-catalyst of cobalt phosphate (CoPi). The nanostructured photoanodes are characterized with a range of electrochemical techniques, such as cyclic voltammetry (CV) and electrochemical impedance spectroscopy. Zn<sub>0.5</sub>La<sub>0.5</sub>TaO<sub>1.5</sub>N<sub>1.5</sub> based photoanodes retain its crystalline structure and it possess the band gap of < 2.6 eV. The oxygen production on the photoanodes is evidenced by sensing oxygen concentration in alkaline solution and under illumination condition. Figure 1a shows the CVs characteristics of Zn<sub>0.5</sub>La<sub>0.5</sub>TaO<sub>1.5</sub>N<sub>1.5</sub> and CoPi/Zn<sub>0.5</sub>La<sub>0.5</sub>TaO<sub>1.5</sub>N<sub>1.5</sub> photoanodes in dark and under illumination and it evidences the potential shift towards the lower potential regions with the additions of CoPi co-catalysts. In addition, photocurrent density of 2 mA/cm<sup>2</sup> was observed for the Zn<sub>0.5</sub>La<sub>0.5</sub>TaO<sub>1.5</sub>N<sub>1.5</sub> photoanodes and it is further enhanced to 5 mA/cm<sup>2</sup> by loading CoPi co-catalyst. Fig. 1b shows the oxygen evolution measurement in a sulphate solution (pH 13) in a two compartment cell under visible light (> 450 nm) with the corresponding chronoamperometric measurements of the photoanodes. The use of photodeposited CoPi co-catalyst on ZnLaTaON together with sulphate solutions significantly increased the photocurrent and enabled us to produce O<sub>2</sub> from water under visible light irradiation at a potential of (1.2 V vs SCE).

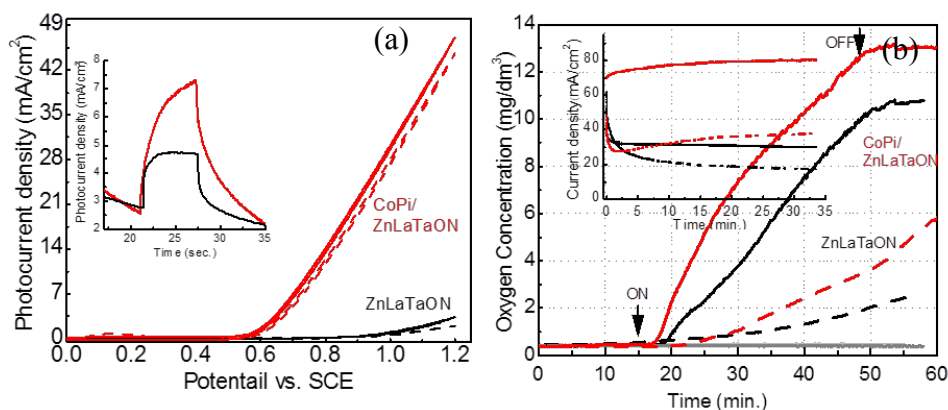

Figure 1: (a) CVs and (b) Oxsense measurements of oxygen at ZnLaTaON with and without CoPi at 1.2 V vs SCE. Dashed line-dark; solid line: light (Inset corresponding CA of the photoanodes).

# Nano-Impacts – Studying Magnetic Field Effects on Single Magnetite Nanoparticles in Solution

Kristina Tschulik, Richard G. Compton

Physical and Theoretical Chemistry Laboratory, Department of Chemistry, University of Oxford, South Parks Road, Oxford, OX1 3QZ, UK  
*Tschulik.Kristina@gmail.com*

Magnetite nanoparticles ( $\text{Fe}_3\text{O}_4$  NPs) have widespread application in magnetic field-based medical treatments, for instance in Magnetic Resonance Imaging (MRI) for diagnostics or in future therapies like targeted drug delivery or hyperthermia. Inferring information on the effects of the applied magnetic fields on nanoparticle agglomeration and thus biodegradation, e.g. in the human body, is therefore an important analytical task.

Two electrochemical ‘nano-impact’ methodologies Anodic (APC) and Cathodic Particle Coulometry (CPC) are presented herein to address these tasks. They enable the detection and sizing of magnetite nanoparticles in a solution on a single particle basis and in the presence or the absence of a magnetic field. Particle Coulometry measures the charge transferred when a particle impacts an electrode that is held at a potential high enough to either reduce (CPC) or oxidize (APC) the impacting particle (Fig. 1). The charge transferred per impact provides the number of atoms in each nanoparticle and thus individual particle sizes and agglomeration states can be determined [1]. For mixed oxides like  $\text{Fe}_3\text{O}_4$  both APC and CPC can be applied complementarily [2]. While the used superparamagnetic  $\text{Fe}_3\text{O}_4$  nanoparticles were found to be stable against agglomeration even in the presence of electrolytes of high ionic strength (0.2 M phosphate buffer), the application of a magnetic field of 0.3 T induced individual nanoparticles to agglomerate to larger clusters in the same electrolyte solution [3]. Furthermore, the dissolution of  $\text{Fe}_3\text{O}_4$  nanoparticles was found to be strongly slowed down in the presence of a magnetic field. This effect is attributed to the high magnetic field gradients established at the nanoparticles’ surface and the associated local action of a magnetic field gradient force retarding the dissipation of the formed paramagnetic  $\text{Fe}^{2+}$  ions from the nanoparticle surface.

Fig. 1: Schematic drawing showing the principle of nanoparticle impact based sizing of individual magnetite nanoparticles via Anodic (left) and Cathodic Particle Coulometry (right).

Graphene oxide (GO) has attracted much attention as a water soluble, highly tunable platform for applications in composites,[1] sensors[2] and biomaterials.[3] The hydrophilic structure of GO is given by epoxy bridges, hydroxyl and carboxyl groups and allows the preparation of aqueous solutions, mainly formed by single layer GO sheets, which can be processed on different substrates,[4] and possibly reduced to obtain conductive reduced graphene oxide (RGO).[5] The complex structure of GO and the large variety of chemical groups present in it require specific techniques to study its properties at the single sheet level. Scanning electrochemical microscopy (SECM) can image GO flakes on insulating and

A SECM image of GO sheet on gold.

conducting substrates. The contrast between GO and the substrate is controlled by the electrostatic interactions that are established between the charges of the molecular redox mediator and the charges present in the sheet. SECM also allowed quantitative measurements of the charge transfer kinetics between single monolayer sheets and redox mediator molecules. By using different redox mediators and different substrates we show the effect of single layer coating on the electrochemical processes that take place on a surface. The charges present on the surface of a monoatomic layer can hinder the SECM current or enhance it. The final contrast is indicative of the state of the sheets and of the electrostatic interactions between the molecular redox mediator and the charges of the sheet surface. [6]

This approach will likely allow to study – with nano/microscale resolution – the electrochemical properties and processes of monoatomic sheets of other 2D materials

such as BN and MoS<sub>2</sub>, in both water and other liquids.

# Preparation, Characterization, and Electrochemical Properties of Monolith Glass-like Carbon-Silica Composites

Jane Karla F.B. Machado<sup>1</sup> and Herenilton P. Oliveira<sup>2</sup>

<sup>1</sup>Universidade de Franca, Av. Dr. Armando Salles Oliveira, 201, Franca (SP), Brazil

e-mail: herepo@ffclrp.usp.br

Polymeric glassy carbon/silica composites were prepared by carbonizing cured pre-polymers from phenolic resins and silica xerogel. The idea behind this study is to obtain a composite electrode through simultaneous polymerization of phenol formaldehyde oligomers and tetraethoxysilane or methyltriethoxysilane monomers forming an interpenetrating hybrid polymer network using soft chemistry approach, followed by controlled heating up to 1200 °C in an oxygen-free environment. The proposed methodology enables to obtain isotropic and monolithic glass-like carbon/silica composite electrodes with high carbon amount (the resultant glassy ceramic composites consist of up to 85 mass% of glassy carbon and 15 mass% of silica) based on phenol-formaldehyde thermosetting resin (Figure 1), and their application as working electrode and as support to chemically modified electrodes. The characterization of the as-synthesized monoliths was carried out by thermal analysis, scanning electron microscopy, X-ray dispersive energy spectroscopy, X-ray powder diffraction, infrared and Raman spectroscopies, and the electrochemical properties were evaluated by cyclic voltammetry as well impedance. X-ray dispersive energy mapping indicates that the silica (presence confirmed by X-ray diffraction patterns) is homogeneously dispersed in the glassy carbon matrix. The electrochemical properties were characterized in NaOH and H<sub>2</sub>SO<sub>4</sub> solution by cyclic voltammetry at different sweep rates in the potential range between the hydrogen and oxygen evolution. The electrode surfaces were evaluated for their electron transfer with Fe(CN)<sub>6</sub><sup>3-/4-</sup> system in aqueous electrolyte (Figure 2), as well as the effects of the different silica precursors on electrochemical properties. Finally, the adopted procedure minimizes the formation of bubbles, cracks and distortions in the material, as well as it is possible to assemble electrodes of different sizes and shapes depending on the geometry of the mold.

In this work we show the direct observation, by means of spectro-photoelectrochemical experiments, of charge transfer between a semiconductor ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) and a metal oxide overlayer (hydrous IrO<sub>x</sub>) as a photoanode architecture in photoelectrochemical water splitting.<sup>1</sup> The aim is to clarify the ambiguous role of oxygen evolving catalysts used as overlayers on top of photoanodes in photoelectrochemical water splitting cells. Previous literature suggested that the real benefit of covering hematite with overlayers like iridium or cobalt oxides is not due to an increase of reaction kinetics but the decrease of the electron density in the hematite<sup>2</sup> or the storage of photogenerated holes.<sup>3</sup> These effects are likely more important when hydrous overlayer, that can act as adapting catalysts,<sup>4</sup> are considered. All these hypothesis can explain the observed improved hole lifetime and reduce recombination with electrons.

The present experimental approach is similar to the one that allowed our recent disclosure of the oxidation states assumed by hydrous IrO<sub>x</sub> as catalyst for water oxidation.<sup>5</sup> In the present case, FEXRAV<sup>6</sup> and XANES have been used to probe changes in the charge state of Ir while the hematite was illuminated with 410nm radiation. Thanks to this *in-operando* setup, we were able to observe an increase of the density of empty Ir 5d states during hematite illumination and in correspondence of water spitting in the photoelectrochemical cell. The main conclusion is that a charge (hole) transfer between hematite and iridium occurs only when the hematite is illuminated. Hydrous iridium oxide is therefore capable of withdrawing holes from the semiconductor thus increasing the probability of interface reaction rather than charge recombination.

Lithium-Ion Battery (LIB) applications for electric vehicles, smart grids etc. have recently attracted much attention. For this purpose, a new class of LIBs with larger capacities and power density as well as higher reliability is quite demanded. It is well known that most of those properties are governed by the quality of solid electrolyte interphase (SEI) film formed on the interface between negative electrode and organic electrolyte. However, the reaction mechanisms around electrolyte-electrode interfaces have not been fully understood yet on the atomic scale due to the difficulty in experimental in-situ observation. Then, we have addressed such unresolved issues by using DFT-MD sampling with sufficient accuracy.

The SEI formation is initiated by the electrochemical decomposition of the electrolyte molecules such as solvents, additives, and Li-salt anions. Slight change of the electrolyte component often exhibits a large impact on the SEI quality. We first examined the reductive decomposition of the electrolyte molecules at charging, namely under reductive environment, using a representative LIB system with ethylene carbonate (EC) solvents and vinylene carbonate (VC) additives on a graphite electrode. We carried out DFT-MD free energy calculations with a cutting-edge Blue-moon ensemble technique for the possible reductive decomposition pathways, together with DFT-MD samplings of probable metastable states. We then found that VC passivation to EC anion radical, a product of one-electron reductive decomposition of EC, is more appropriate mechanism than the conventional scenario with sacrificial reductive decomposition of VC (Fig. (a)) [1]. This novel mechanism can explain the decrease of irreversible capacity and the CO<sub>2</sub> evolution with a small amount of VC additives observed experimentally, and the concept has been supported by subsequent studies.

Next, we extracted stable SEI film components (SFCs) from the products of the reductive decompositions of the electrolyte molecules. We then investigated the characteristic of the SFC monomers as well as the probable SFC amorphous aggregates on the adhesion to the graphite electrode and the interfacial electronic states. The results showed that the SFC aggregates are characterized by “unstable adhesion” to the graphite surface (Fig. (b)) and “high electronic insulation”. With these results, we discussed the mechanism how the SFC aggregates are formed toward the SEI film formation [2]. These new findings will contribute to the development of more efficient and reliable LIBs.

Figure (a) Schematic mechanisms of the initial reductive decompositions in the electrolyte with EC solvents only and the EC solvents with VC additives. (b) A snapshot of the adhesion of SFC aggregate to the graphite electrode.

# Photoelectrochemical Response of Hetero-layer Films Composed of Redox-active Ru Complexes: Charge Trapping and Memory Effect

Masa-aki Haga, Takumi Nagashima, Hiroaki Ozawa

Department of Applied Chemistry, Chuo University, 1-13-27 Kasuga, Bunkyo-ku, Tokyo 112-8551, Japan  
E-mail: mhaga@kc.chuo-u.ac.jp

Sequential layer-by-layer assembly by coordination bond is of great scientific and practical importance due to a promising method for the construction of well-ordered layered structures on a solid surface. Combining with two components with different redox potentials, many layer structures with different potential gradients can be constructed. Here, two dinuclear Ru complexes, Ru-NP and Ru-CP, were selected as shown in Fig 1, in which the oxidation potentials are  $E_{1/2} = +0.84$  and  $+1.06$  V vs  $\text{Fc}^{0/+}$  for Ru-NP, and  $E_{1/2} = -0.40$  and  $0.07$  V for Ru-CP, respectively.[1] The structure of the multilayers is described as  $\text{ITO}||(\text{Ru-NP})_n(\text{Ru-CP})_m$ , where the subscript “n or m” represents the number of Ru layers connected by the Zr layer. Two heterolayer films were chosen: i.e., one structure was  $\text{ITO}||(\text{Ru-NP})_n(\text{Ru-CP})_m$ , and the other was  $\text{ITO}||(\text{Ru-CP})_n(\text{Ru-NP})_m$ . In the hetero-layer films of  $\text{ITO}||(\text{Ru-NP})_4(\text{Ru-CP})_4$ , cyclic voltammogram showed a typical catalytic wave, resulting from the rectification of electron transfer due to the large potential difference between Ru-NP and Ru-CP, and the charge was trapped in the outer layers. This charge trapping process in the outer Ru-CP layer was proved by the observation of the intervalence charge transfer (IVCT) band at 1140 nm in the thin-layer film spectroelectrochemistry. Under photocurrent measurements on the  $\text{ITO}||(\text{Ru-NP})_4(\text{Ru-CP})_4$  film, the direction of photocurrent was governed by the charging state of the outer Ru-CP layers; i.e., when the Ru-CP layer possessed the discharging Ru(III)-Ru(III) state, a *cathodic photocurrent* was observed, but once the Ru-CP layer became charged as a mixed-valent Ru(II)-Ru(III) state, the photocurrent direction was changed to anodic. Since the charging/discharging of the outer Ru-CP layer was controlled by altering the potential from -0.5 V to 0.7 V, the present hetero-layered films acts as a memory device. (See Fig 2) When the sequence of the layers was inverted from  $\text{ITO}||(\text{Ru-NP})_4(\text{Ru-CP})_4$  to  $\text{ITO}||(\text{Ru-CP})_4(\text{Ru-NP})_4$ , the photocurrent response became reverse as an *anodic photocurrent*. Therefore, the molecular sequence plays an important role in the hetero-layer films composed of the Ru complexes.

Fig1. Chemical Structures of two Ru complexes, Ru-NP and Ru-CP, and schematic drawings for two different hetero-layer structures linked by Zr ion: i.e.,  $\text{ITO}||(\text{Ru-NP})_4(\text{Ru-CP})_4$  (left)  $\text{ITO}||(\text{Ru-CP})_4(\text{Ru-NP})_4$  (right side).

Fig 2. Potential pulse pattern (red line) and concomitant photoirradiation pattern (violet line) and resulting photocurrent response on heterolayer  $\text{ITO}||(\text{Ru-NP})_4(\text{Ru-CP})_4$ .

Two dimensional layer-structured transition metal dichalcogenides has recently received much attention, due to their specific optical, electronic and mechanical properties resulting from their unique structures [1,2]. This is related to their physicochemical characteristics resulting from the specific structure consisting covalently bonded metal atoms sandwiched between chalcogen layers [2]. MoS<sub>2</sub> is the most extensively studied material from this class and its application in lithium ion batteries [3] and as hydrogen evolution catalyst [4] was reported. The limitations of electrochemical applications of this material were also pointed out [5]. MoS<sub>2</sub> can be decorated with other nanomaterials, for example gold nanoparticles. Such hybrid material was reported to exhibit electrocatalytic synergy in dioxygen reduction reaction [6] or oxidation of ascorbic acid, dopamine and uric acid oxidation for selective sensing [7].

Here we will report preparation and characterisation of MoS<sub>2</sub> nanopetal stacks decorated with carbon and gold nanoparticles and the application of these materials in electrocatalysis of biologically active compounds. The decoration of MoS<sub>2</sub> with negatively and/or positively charged carbon nanoparticles was performed in suspension of both substrates by sonication and the obtained material was characterised by dynamic light scattering. The hybrid material was deposited on the electrode (glassy carbon) by drop casting. On the other hand MoS<sub>2</sub> nanopetal stacks decorated with positively charged Au nanoparticles were directly formed on the electrode (ITO) surface by alternate dropcasting of both components suspension. The films of both hybrid materials were characterised by scanning electron microscopy, X-ray photoelectron spectroscopy and Fourier transformed infrared spectroscopy.

Cyclic voltammetry reveals that modification of the electrode substrate produce an increase of electrochemically active surface and increase electronic conductivity of MoS<sub>2</sub>. The decoration of MoS<sub>2</sub> with carbon nanoparticles produces material with electrocatalytic activity towards neurotransmitters as epinephrine or dopamine. In turn the hybrid material consisting MoS<sub>2</sub> nanopetals stacks decorated with Au nanoparticles exhibits electrocatalytic activity towards cysteine, glutathione and glucose. This activity depends also on the functionalisation of Au nanoparticles used for decoration.

The growing need for energy on global scale and the realization that the so called oil-based economy cannot sustain our world anymore, prompted researchers to find new ways to “power” the planet.<sup>1</sup> In particular a lot of efforts have been done in the field of chemical energy conversion, that remains very challenging because of the requirement for higher efficiencies.<sup>2</sup> Over the last decades the continuous increase of carbon dioxide in the biosphere has been recognised as one of the main causes for the global warming. The conversion of carbon dioxide into chemical fuels is a topic of great interest and recently a lot of different approaches for the electrochemical reduction of this powerful greenhouse gas to more useful products have been reported.<sup>3</sup>

In this context our group recently focused the attention on the study of catalytic systems for the splitting of water.<sup>4</sup> Our last efforts have been done in the design and development of new nanostructured material that synergistically combine the unique properties of multiwall carbon nanotubes (MWCNTs), metal oxides (CeO<sub>2</sub>) and Pd nanoparticles (Pd NPs).<sup>5</sup> The MWNT@Pd/CeO<sub>2</sub> nanomaterial have been designed and evaluated as electrocatalyst for the CO<sub>2</sub> conversion.

This nanohybrid exhibit very good performances and efficiencies, showing physical and chemical properties that differ to those expected from the simple sum of the individual building blocks. Finally, we shed light on the role of the Pd NPs in terms of their influence on the electrocatalytic activities.

The electrochemical properties of noble-metal nanocrystals strongly depend on their shapes and sizes. Therefore, shape-controlled and size-controlled syntheses of noble-metal nanocrystals have been extensively studied.<sup>1,2</sup> We introduce here some methods, such as seed-mediated growth methods, hydrothermal methods and diazonium methods, for the synthesis of high-quality noble metal nanocrystals, such as rhombic dodecahedral, cubic, and octahedral gold and palladium nanocrystals, as well as many derivatives with varying degrees of edge- and corner-truncation,<sup>3,4</sup> convex hexoctahedral palladium@gold core-shell nanocrystals with {431} high-index facets,<sup>5</sup> platinum highly concave cube with one leg on each vertex,<sup>6</sup> and porous PtM (M=Cu, Ni) nanowires<sup>7</sup> developed during the past few years. The electrocatalytic properties of the as-prepared nanostructures toward alcohol oxidation and electrochemiluminescent reactions will be demonstrated.<sup>8</sup>

# Electrochemical Synthesis of Red Fluorescent Graphene Quantum Dots for the Bioimaging Platform

Louzhen Fan\*, Xiaoyun Tan, Ruihua Guo

Department of Chemistry, Beijing Normal University, Beijing, China, 100875

lfan@bnu.edu.cn

Graphene quantum dots (GQDs) have attracted much recent attention due to their ultrafine dimensions, tunable surface functionalities and economical synthetic routes. The stable photoluminescence (PL) and low toxicity make them outstanding as an alternative to organic dyes and inorganic quantum dots (QDs) in biological applications.<sup>1</sup> On the other hand, due to the auto-fluorescence and light scattering background of biological specimens in the short-wavelength region, fluorescent materials of choice are expected to emit in the long-wavelength region in order to provide a deeper light penetration into the specimens, resulting in a higher imaging contrast. To date, most of the reported GQDs emit the blue to green fluorescence, which usually exhibits excitation wavelength dependence<sup>2</sup>. Herein, we report the facile electrochemical exfoliation of graphite in  $K_2S_2O_8$  solution for the synthesis of uniform small-sized red fluorescent GQDs (RF-GQDs) without any chemical modification, which has been used for cellular imaging.<sup>2</sup>

Figure 1. (a) Confocal fluorescence microscopy images of HeLa cells with RF-GQDs incorporated at the excitation wavelength of 488 nm, (b) Spectra of RF-GQDs aqueous solution. The inset of (b) is the photograph of the RF-GQDs solution under day light and 365 nm illumination.

# **Development of Multifunctional Materials Composed of Selected Noble Metal and Metal Oxide Nanostructures for Efficient Electrocatalytic Oxidation of Small Organic Molecules**

Iwona A. Rutkowska\*, Pawel J. Kulesza

*Faculty of Chemistry, University of Warsaw, Pasteura 1, PL-02-093 Warsaw, Poland.*

*\*ilinek@chem.uw.edu.pl*

Certain organic fuels that include formic acid, methanol, dimethyl ether or ethanol are presently considered as alternatives to hydrogen for application in low-temperature fuel cells. Although all of them can be ideally oxidized to carbon dioxide, their actual electrooxidation mechanisms can significantly differ and may result in distinct electrocatalytic efficiencies and final reaction products. There is a need to develop multifunctional electrocatalytic systems exhibiting specific reactivity and capability to induce the slow reaction steps at ambient conditions.

Platinum or palladium-based nanoparticles have been recognized as the most active catalytic systems towards oxidation of small organic molecules at low and moderate temperatures. Noble metal nanoparticles are readily poisoned by the strongly adsorbed CO-type intermediate species requiring fairly high overpotentials for their removal. For example, to enhance activity of Pt-based catalysts toward the ethanol oxidation, additional metal or metal oxide nanostructures (rhodium, iridium, tin or molybdenum and tungsten oxides) will be intentionally introduced to the electrocatalytic interface. We are also going to demonstrate that catalytic activity of platinum-based nanoparticles towards electrooxidation of ethanol can be significantly enhanced through their interfacial modification with ultra-thin monolayer-type films of mixed metal oxo species of tungsten, titanium, cerium or zirconium. Remarkable increases of electrocatalytic currents measured under voltammetric and chronoamperometric conditions have been observed. The most likely explanation takes into account possibility of specific interactions of noble metals with transition metal oxide species as well as existence of active hydroxyl groups in the vicinity of catalytic noble metal sites. It is noteworthy that certain metal and mixed-metal oxides can generate –OH groups at low potentials: they induce oxidation of passivating CO adsorbates (e.g. on Pt) or breaking C-H bonds (e.g. during oxidation of methanol or dimethyl ether). When combined with dispersed Rh or Ir, they tend to weaken C-C bonds during ethanol oxidation.

# Simultaneous Covalent Assembling of Two Different Organic Films on Glassy Carbon Using Bipolar Electrochemistry

Line Koefoed,<sup>1</sup> Kyoko Shimizu,<sup>1</sup> Steen Utrup Pedersen,<sup>1</sup> Kim Daasbjerg,<sup>1</sup> Alexander Kuhn,<sup>2</sup> Dodzi Zigah<sup>2</sup>

line88@chem.au.dk

Bipolar electrochemistry is a well-established technique which, recently, has attracted renewed interest in various fields, including fabrication of Janus particles.<sup>[1]</sup> The versatility of this technique allows several kind of surface modifications to be carried out, including direct reduction of metal ions to form the corresponding metal deposit,<sup>[2]</sup> fabrication of both gradient and patterned polymer brushes,<sup>[3]</sup> and oxidation of monomers to electrogenerate polymer films.<sup>[4]</sup>

In this study a novel methodology is reported, which for the first time allows simultaneous deposition of two different organic films at each end of a glassy carbon substrate ( $1 \times 1 \text{ cm}^2$ ). The approach is based on the use of an organic bifunctional molecule, i.e., 4-(2-aminoethyl)benzenediazonium, which may be reductively and oxidatively grafted at the same time using bipolar electrochemistry (Scheme 1). The reduction process goes through the diazonium group while the oxidation proceeds via the primary amine. The double functionalized plates are investigated by ellipsometry, cyclic voltammetry, condensation imaging, x-ray photoelectron spectroscopy, and time-of-flight secondary ion mass spectrometry. Post-modification of one of the anchoring layers illustrates the versatility of the system, pointing to its potential use in fields going from molecular electronics to targeted drug delivery. Furthermore, it is shown that the new technique is not limited to glassy carbon as substrate, but that it works equally well for, e.g., transferred graphene.

**Scheme 1.** Simultaneous grafting of two different organic films on glassy carbon using bipolar electrochemistry.

Electroactive materials containing the porphine macrocycle in their structure are actively studied in view of their applied prospects in electrocatalysis, photocatalysis, sensors, solar energy conversion, non-linear optics, etc. Porphine unit is present in most systems in its monomeric form, e.g. as a pendant group of a polymer chain. There are a few examples of copolymers possessing a well-defined molecular structure of alternating porphyrin and (hetero)aromatic units which are mostly synthesized by organometallic catalysis. On the contrary, molecular structures of polymer films deposited by direct oxidation of substituted porphyrins on electrode surface were not determined.

Our team succeeded in synthesis of the first homopolymer (pMgP-I) on the basis of non-substituted Mg(II) porphine (MgP, Fig. 1a) [1]. This polymer has been characterized by combination of methods of electrochemistry, spectroscopy and microscopy which demonstrated that it represents a typical electroactive material, i.e. it can be charged and discharged in a quasi-reversible manner by means of the potential variation (within certain limits), this variation of the oxidation state being accompanied by the drastic change of its redox, conductive and spectroscopic properties. IR spectra, XPS and electrochemistry data [1] testify in favor of conservation of both the porphine macrocycle as monomer unit and Mg cation inside this material. However, the way of their bonding in the polymer was unclear.

Fig.1. Mg(II) porphine (a) and hypothetic structures of its polymer: linear chain (b) or 2D structure (c). Evolution of the UV-visible spectrum of MgP solution in the course of its oxidative electrolysis (d).

The goal of the actual study has been to get direct information on the average number of bonds inside this polymer, which are formed by each porphine species in the course of its oxidative transformation from the monomeric state in solution to the monomer unit inside the polymer. Our approach is based on fundamental principles of electrochemical polymerization processes, in particular, those resulting in deposition of electroactive polymer films on electrode surface, which relate the amounts of the consumed monomeric reactant, of the reaction product(s) and of the electric charge spent for this process via **stoichiometric** relations. Reliable experimental determination of their parameters may be used both to get conclusions on the molecular structure of the polymer and to estimate the current efficiency of the polymer film formation as well as the maximal degree of the polymer oxidation.

The amount of oxidized monomer species may be determined from the temporal evolution of the spectrum of the electrolyzed solution in the UV-visible range (Fig. 1d). Its relation to the passed electric charge has been used to calculate the number of chemical bonds that a monomer porphine unit inside the polymer/oligomer structure forms with neighboring monomer units (Fig. 1b vs. Fig. 1c). Conclusion on the chain structure of the Mg(II) polyporphine has been made on the basis of these data.

Galvanic displacement reaction (GDR) is potentially one of the most efficient methods to decorate 3D porous electrodes with noble metal nanoparticles. In the last few years, we studied GDR processes and we applied it to modify several 3D substrates, including Ni porous layers, Ni foams, FeCrAlloy foams, with noble metals like Pt, Pd, Rh [1].

In the present communication, we describe the use of galvanic displacement reactions for the deposition of Ag nanostructures onto two substrates: (i) commercial Ni foams and (ii) high surface area 3D Ni electrodes obtained by the electrodeposition of thin Ni layers on carbon felts [2]. Several experimental variables, like bath composition, temperature, chemical activation of the Ni surface, and reactant diffusion, influence the GDR, yielding deposits with different characteristics. These variables must be accurately selected to optimize the surface/loading ratio of silver.

The Ag deposits shown in the SEM images below were obtained, from left to right, from a thiosulfate bath, from a thiocyanate bath without Ni activation and from a thiocyanate bath after Ni activation in 1M HNO<sub>3</sub>. Clearly, a strong correlation was observed between silver complexing agents and nanostructures morphology. Reactant diffusion affected the homogeneity of distribution of Ag nanoparticles on inner/outer parts of 3D electrodes.

Since Ag is an active cathode for dehalogenation of organic compounds [3], e.g. pesticides, Ag-modified electrodes were tested as electrocatalysts for the dechlorination of organic pollutants. Cyclic voltammetries in aqueous and organic media were performed to underline the electrocatalytic activity of the modified electrodes toward dehalogenation. Electrolyses were performed in a flow cell in aqueous medium. Preliminary results showed an improved conversion for Ag modified 3D Ni electrodes over unmodified electrodes.

We report the use of Cu<sub>2</sub>O nanoparticles synthesized from simple and cheap copper salts as effective catalyst for electrochemical reactions of great interest, such as water and glucose oxidation. These nanostructured materials with varying shapes (spheres, cubes and octahedrons) but the same size, Figure 1, were prepared by a facile method in the presence of sodium dodecyl sulfate (SDS) surfactant and hydroxylamine.

Figure 1

The nanoparticles were characterized by X-Ray powder diffraction (XRD), scanning electron microscopy (SEM) and Atomic force microscopy (AFM).

The nanoparticles were deposited by casting onto vitreous carbon electrodes, taking care to maintain the same amount of copper, measured by ICP-OES, in each electrode.

All three different shaped Cu<sub>2</sub>O materials showed catalytic activity for both, glucose and water oxidations. The influence of different shapes and sizes on the catalytic activity of both reactions is analyzed.

In the case of glucose oxidation, it was observed a much higher catalytic activity for octahedrons than the other forms but this activity was different for water electrolysis, at different pHs.

The very controlled geometry of these nanoparticles expose different crystallographic planes which could be selectively active for different electrochemical reactions.

Figure 2 shows the X-Ray diffraction patterns of different nanoparticles where it can be observed that

Figure 2

the geometry define the structure of each nanomaterial. The importance of controlling the synthetic parameters for obtaining well-designed catalysts is emphasized in this work.

# Evaluation of bifunctional electrocatalysts for oxygen reduction and evolution by means of scanning electrochemical microscopy (SECM)

The development of electrocatalysts that can reversibly reduce oxygen and oxidize water are of prime importance for the advancement of new emerging electrochemical energy storage and conversion systems, especially in rechargeable metal-air batteries and reversible fuel cells. Rotating disc electrode (RDE) and rotating ring-disc electrode (RRDE) voltammetry are the most commonly used techniques for studying the kinetics and selectivity of oxygen reduction and oxygen evolution catalysts. However, these techniques suffer from drawbacks when applied to non-flat or non-smooth catalytic surfaces due to non-defined flow of the electrolyte through the catalyst film, the prevalence of local turbulences and dissimilarity between the effective electrocatalytically active surface area and the geometric area of the electrode, which lead to inaccurate kinetic and mechanistic assumptions, particularly, the quantity of hydrogen peroxide generated and the average number of electrons transferred. This drawback can be circumvented by applying scanning electrochemical microscopy (SECM) to study the selectivity of ORR, where the tip of the SECM is brought in close proximity to the electrocatalytic surface, to serve as a sensor for O<sub>2</sub> in the redox competition mode of SECM (RC-SECM), or for H<sub>2</sub>O<sub>2</sub> detection in the sample generation-tip collection (SG-TC) mode.

We present the application of scanning electrochemical microscopy (SECM) for characterization of bifunctional catalysts. By using model bifunctional catalysts based on oxides of cobalt (Co<sub>x</sub>O<sub>y</sub>) and nickel (Ni<sub>x</sub>O<sub>y</sub>) embedded in nitrogen-doped carbon (NC), we specifically show the unique ability to determine most of the important electrocatalytic parameters including the selectivity of the oxygen reduction reaction (ORR).

The initial mechanistic steps during the oxygen evolution reaction (OER), and the onset potential for both ORR and OER can be reliably determined in a single SECM experiment. We were able to directly observe that prior to oxygen evolution, local depletion of oxygen occurs at the SECM tip during redox transition accompanying metal oxyhydroxide formation thus enabling direct *in-situ* observation of the initial mechanistic steps of the OER. This is critical for the assessment and development of new generations of bifunctional oxygen electrodes for energy applications.

Example of the response of the SECM tip current during the OER at a Ni<sub>x</sub>O<sub>y</sub>/NC sample.

# Effect of Electrode Surface-State Change on Electrogenenerated Chemiluminescence from a Ruthenium-Doped Silica Nanoparticle

## 1. Introduction

Electrogenenerated chemiluminescence (ECL) is widely studied due to its high performance in analytical applications and complicated reaction mechanism. It has been recently reported that Ru(bpy)<sub>3</sub><sup>2+</sup>-doped silica nanoparticles (Ru-DSNPs) generate efficient ECL by applying anodic potentials under the presence of tripropylamine (TPA) [1]. Numerical modeling is a powerful tool to clarify complicated reaction mechanism. In this study, we investigated numerical modeling of ECL from a Ru-DSNP in TPA-containing buffer, focusing on electrode surface-state change caused by the anodic potential application.

## 2. Experimental

We used COMSOL Multiphysics® (version 3.5a) for our modeling mainly considering the Butler-Volmer equation and Fick's law of diffusion. A Ru-DSNP with a diameter of 18 nm was placed on the center of a working electrode with a diameter of 0.5 mm. Representative modeling parameters are shown in Table 1 [1-3]. Electrochemical measurements were carried out with the Bio-Logic SP-300 potentiostat.

## 3. Results and discussion

Figure 1 shows simulated ECL behaviors as a function of applied potential. First we carried out simulations using two constants suggested in the related studies; however, we could not well simulate rapid ECL decay at >0.9 V vs. Ag|AgCl observed in the experimental study. Chen et al. have suggested that the deprotonation of TPA radical cation on working electrode become faster after oxidizing the electrode surface [4]. On the other hand, our electrochemical measurements indicated Ru-DSNPs would be detached and then the electrode surface would be oxidized at >0.9 V. Considering these findings, we made the deprotonation equilibrium of TPA radical cation dependent on the applied potential to simulate the dynamic electrode surface-state change. Finally, we found out the ECL behavior for the Ru-DSNP was well simulated by increasing forward rate constant for the equilibrium during potential application.

## 4. Conclusion

This study suggests that electrode surface-state change during potential application should be carefully considered in analysis for ECL generation.

Table 1. Representative modeling parameters.

	reaction	modeling parameters
1	$\text{TPA} \rightarrow \text{TPA}^{++} + \text{e}^-$	$k_s^{\text{TPA}} = 10 \text{ cm s}^{-1}$ $E_{\text{TPA}}^0 = 0.88 \text{ V}$
2	$\text{TPA}^{++} \leftrightarrow \text{TPA}^{\bullet+} + \text{H}^+$	$k_f^{\text{TPA}} = 540 - 3500 \text{ s}^{-1}$ $k_b^{\text{TPA}} = 1.08 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$
3	$\text{TPA}^{\bullet+} + \text{Ru}(\text{bpy})_3^{2+} \rightarrow \text{P1} + \text{Ru}(\text{bpy})_3^{3+}$ (P1: $\text{Pr}_2\text{N}^+\text{C}=\text{HCH}_2\text{CH}_3$ )	$k_f^1 = 10^{10} \text{ M}^{-1} \text{ s}^{-1}$
4	$\text{TPA}^{++} + \text{Ru}(\text{bpy})_3^{3+} \rightarrow \text{TPA} + \text{Ru}(\text{bpy})_3^{2+*}$	$k_f^2 = 10^6 \text{ M}^{-1} \text{ s}^{-1}$
5	$\text{Ru}(\text{bpy})_3^{2+*} \rightarrow \text{Ru}(\text{bpy})_3^{2+} + \text{ECL}$	$k_f^{\text{ECL}} = 10^{7.2} \text{ s}^{-1}$

Symposium 14:

Modeling, Design and Characterization of Nanostructured, Electroactive and Multifunctional Materials

Bulk and surface electrochemical reactivity converge on ultrathin electrochemical interfaces such as single layer graphene (SLG) the world's thinnest electrode, and few layer graphene (FLG).[1] We will demonstrate that these materials enable unique chemical interactions that operate at scales coincident with their thickness. These electronic and chemical interactions result in enhanced rates of electron transfer for electrocatalytic processes. Thus, beyond its superior electronic properties, ultra-thin carbons permit a wide array of chemistries that enable new interactions in electrocatalysis.

We will discuss our results on the electrochemistry of  $\text{cm}^2$ -large SLG and FLG with a well-controlled morphology produced via chemical vapor deposition in our laboratory. This material yields electrode surfaces that are easy to transfer and to address electrochemically in aqueous and nonaqueous electrolytes, with a well-defined area and clean contacts [2,3]. Using scanning electrochemical microscopy (SECM), we demonstrate unambiguously that SLG electrodes deposited over micro-patterned metallic substrates exhibit facilitated electron transfer to mediators in solution. For instance, the reaction of the ferri/ferrocyanide redox pair which is notoriously slow on pristine SLG [3] is dramatically accelerated on Au/SLG spots as shown in **Figure 1** via feedback SECM measurements. These interactions were further used to tune the reactivity of molecular adsorbates on SLG for the oxygen reduction reaction (ORR). Our results indicate that the nature of the underlying metal has a profound impact on the electrochemical potential for the ORR and its mechanism. These observations strongly suggest that SLG and FLG used as carbon supports, far from a role as spectator materials, might engage actively by facilitating electrocatalytic reactions on a larger area than the nominal metal/graphene interaction. The strategy presented here suggests new methods by which metal-molecule interactions can be stabilized by ultra-thin carbons. For instance, metals prone to corrosion or prone to poisoning can be protected while permitting some degree of interaction with the electrolyte. The new strategies will be critical in the creation of new bulk materials with tailored properties.

# Electrical Characteristics of Raw Si-based Powders for Li-ion Electrode by Kelvin Probe Force Microscopy (KPFM) and Electrostatic Force Microscopy (EFM)

Jing-Ting Liao(廖敬庭), Sin-Syu Liao(廖信旭), Bernard HaoChih Liu(劉浩志)†

*Department of Materials Science and Engineering, National Cheng Kung University, Taiwan*

*†Corresponding author, Tel : (06)2757575#62926 , E-mail address: hcliu@mail.ncku.edu.tw*

As there are many components in a Li-ion battery system, such as electrode materials, binders and additives, it is hard to analyze the individual contribution of raw materials to the battery performance. In this research, we utilized scanning probe microscopy (SPM) to analyze raw Si-based powders for electrode materials directly. We used Kelvin probe force microscopy (KPFM) and electrostatic force microscopy (EFM) to measure microscopic electrical properties and topography at nanoscale simultaneously. The preliminary measurement results are shown below, and we will discuss the relation among work function, particle size and roughness of raw materials. The aim is to evaluate the advantages and disadvantages of electrode materials before battery assembling and reduce the complexity of the whole battery analysis. This approach will assist manufacturers in the control of raw material quality as well as that of the production lines.

**Keywords:** raw electrode materials, Kelvin probe force microscopy, electrostatic force microscopy, microscopic electrical property

\*E-mail: kcho@ntu.edu.tw

Conducting polymers have been extensively investigated in the field of electrochemistry, particularly involving electrochromism. Among these conducting polymers, polyaniline (PANI) has been regarded as a promising material for electrochromic thin films due to its low cost, excellent redox reversibility and facile synthesis. However, it still possesses undesirable features such as poor cycling stability and long coloration time.

Several strategies have been proposed to improve the electrochemical performance of the PANI-based thin films. Recently, Wang *et al.* synthesized the one-dimensional (1-D) nanorods of a cross-linked copolymer constructed from aniline, triphenylamine (TPA), and p-phenylenediamine (PPDA) [1]. Thin films of the obtained copolymer were found to exhibit a better electrochemical stability due to the cross-linked nature, thus can be applied for supercapacitors. However, the reported thin film was prepared by physically depositing the PANI-based nanorods onto the underlying electrode with random orientation. Since the 1-D nanowire arrays of an electrochromic material have been proved to shorten the coloration time through easier ion diffusion [2], it is reasonable to consider that the 1-D nanorod arrays of such PANI-based cross-linked copolymers chemically grown on conducting substrates may exhibit both the stable electrochemical performance and fast redox switching.

Herein, 1-D nanorod arrays of a cross-linked PANI-based copolymer (c-PANI) were grown on the conducting glass by using an *in-situ* chemical polymerization in the solution containing aniline, TPA and PPDA (Fig. 1(a)). The self-assembled monolayer (SAM) was utilized to chemically bond the conducting glass and the c-PANI thin film, which is expected to further enhance the stability of the electrode and reduce the charge-transfer resistance at the interface. A higher utility in redox reaction was thus obtained by the c-PANI thin film compared to the electropolymerized flat PANI thin film (Fig. 1(b)). Interestingly, a significant difference in spectroelectrochemical response was observed, which indicates that the c-PANI film has a higher absorbance below 400 nm and a lower absorbance in the visible range (Fig. 1(c)); this observation is attributed to the existence of TPA and PPDA. The higher absorbance change of the c-PANI thin film between 0 and -0.6 V at around 450 nm (Fig. 1(c)) offers the potential application of the c-PANI thin film for electrochromic devices.

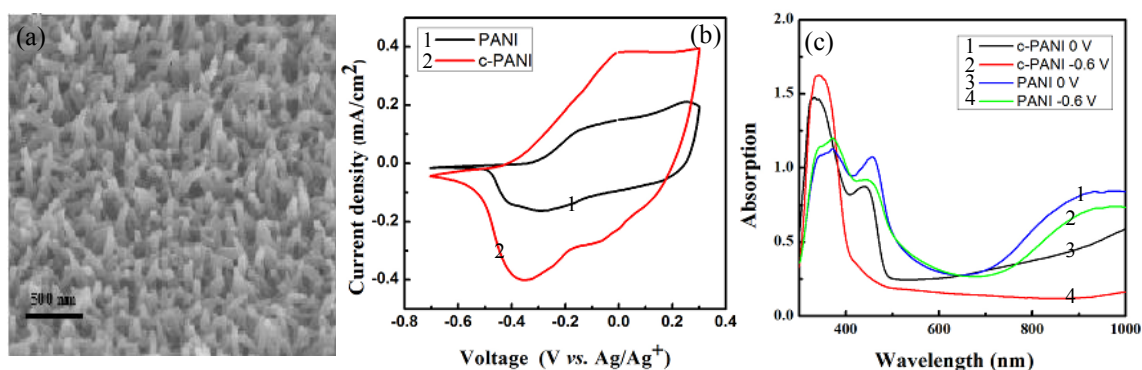

Figure 1 (a) Electron microscopic image of the nanorod arrays of c-PANI. (b) Cyclic voltammograms of the flat PANI and c-PANI measured in LiClO<sub>4</sub>/propylene carbonate. (c) UV-vis spectra of the PANI and c-PANI measured at 0 V and -0.6 V.

Hollow carbon nanoparticles with uniform and interconnected pore networks are considered as promising candidates for supercapacitor electrodes since they can provide excellent capacitive performance owing to their high surface area, large pore volume and uniform pore size distribution. Working as candidates for supercapacitor electrodes, hollow carbon nanoparticles needs high specific capacitance, long cycle life, high power density, short charge/discharge time. Consequently, a high current density through hollow carbon nanoparticles may occur due to short charge/discharge time. If the high current density-induced heat in hollow carbon nanoparticles does not be well released, it will result in temperature rise of hollow carbon nanoparticles and reduce the performance of electrode. Therefore this project will investigate the electrical heating effects in hollow carbon nanoparticles with high current density in charge/discharge process of electrode. The nanoscale thermal transport models will be employed to analyze the high current density-induced electrical heating effects in hollow carbon nanoparticles. The effects of various parameters on electrical heating in hollow carbon nanoparticles will be also discussed.

e-mail: lauranovais@hotmail.com

It is described the synthesis, magnetic and electrical properties of a new iron oxide/polymeric glassy carbon nanocomposite formed by means of a carefully heating of a premodelled polymeric phenol-formaldehyde resin matrix with iron ion dispersed in a citric acid-polyethylene glycol resin in a nitrogen atmosphere. The obtained specimens were analyzed by magnetic measurements using a Quantum Design MPMS-5S SQUID Magnetometer. It is shown that structural characterization by X-ray diffraction reveals the presence of magnetite, Fe and CoC phases dispersed in the glassy carbon matrix. SEM, EDS, FT-IR, AFM, TGA/DTA were used to characterize the composite. For magnetization as function of applied field ( $M$  vs  $H$ ) taken at 10 K a ferromagnetic response was observed with a coercive field ( $H_r$ ) close to 725 Oe and saturation magnetization ( $M_s$ ) around 0.036 emu. In addition, for measurements at 300 K an enhancement of an antiferromagnetic signal was observed with a coercive field ( $H_c$ ) close to 265 Oe. Further, the response of magnetic iron oxide-polymeric glassy carbon nanocomposite to the external magnetic field can also be visualized, thus providing that the iron oxide phase would lead to higher magnetization. The electrochemical behavior of both materials by using hexacyanoferrate and ferrocene systems is quite similar to glassy carbon, as evaluated by cyclic voltammetry and chronoamperometry experiments. In addition, the obtained nanocomposite is thermally stable under air atmosphere up to 600 °C and decomposes slightly up to 1050 °C under inert condition. In conclusion, these materials present thermal stability, robustness, mechanical strength, electrical conductivity, large potential range as well as magnetic properties. Besides, glassy polymeric carbon matrix maintains functional surface groups such as carboxyl and hydroxyl. In fact, these set of experiments were profitable, and they indicate new possibilities to modify the properties leading to multifunctional materials as well as explore new applications.

mivo2010@yandex.com

Electroactive materials produced by introduction of porphyrin macrocycle into conjugated polymer film as a counter ion or by covalent bonding with active groups of the polymer are of great practical interest. A new high-efficiency method of Mg(II) porphine (**MgP**) synthesis has recently been developed [1] and homopolymers of Mg(II) porphine (**pMgP**) with original optical and electrical properties were obtained [2].

The goal of this research is the investigation of the influence of various solvents on the electropolymerization process of MgP and properties of electroactive polyporphine films deposited on electrode surface.

Acetonitrile, dichloromethane and dimethyl sulfoxide were used as the solvent for electropolymerisation bath. The process of MgP-electrodeposition was carried out in potentiostatic regime at low values of oxidation potential with transmission of the constant number of electricity - 120  $\mu\text{C}$  (Fig. 1a). CVA within the narrow and wide potential intervals was used for polymer films characterization (Fig. 1b-c).

Fig.1. Chronoamperometric curves of MgP electrooxidation in acetonitrile, dichloromethane, dimethyl sulfoxide (a). CV-responses of pMgP films in monomer-free solution (MeCN + TBAPF<sub>6</sub>) within the narrow (b) and wide (c) potential intervals.

Among three studied solvents with low content of water, acetonitrile is especially well suited for the electropolymerization of MgP because in acetonitrile solutions the thickness of the polymer film on the electrode surface uniformly increases in potentiostatic regime.

Polymer films, obtained in acetonitrile solutions at low values of oxidation potential show stable CV-response in monomer-free acetonitrile solution within the narrow and wide potential intervals and including large negative values of the potential.

The electropolymerization of MgP in dichloromethane solutions leads to the slow growth of the polymer film on the electrode surface. Moreover, the CV-response of such films in monomer-free solution is unstable and varies during execution of multiple cycling. Polymer films, obtained in dimethyl sulfoxide solutions have a small thickness and therefore low current response. All these films have a completely different redox-properties. pMgP films deposited in DMSO and DCM reveal less intensive current response due to following reasons: 1) partial blocking of the surface of electrode for-electronic transport 2) formation more stable and soluble intermediates (cation-radicals, oligomers etc.) during electropolymerization leading to decrease of its efficiency.

Despite nanomaterials with unique properties playing a vital role in scientific and technological advancements of various fields including chemical and electrochemical applications, the scope for exploration of nano-scale applications is still wide open. The intimate correlation between material properties and synthesis in combination with the urgency to enhance the empirical understanding of nanomaterials demand the evolution of new strategies to promising materials. Herein we introduce a rapid pyro-synthesis that produces highly crystalline functional nanomaterials under reaction times of a few seconds in open-air conditions. The versatile technique may facilitate the development of a variety of nanomaterials and, in particular, carbon-coated metal phosphates with appreciable physico-chemical properties benefiting energy storage applications. The present strategy may present opportunities to develop “design rules” not only to produce nanomaterials for various applications but also to realize cost-effective and simple nanomaterial production beyond lab-scale limitations.

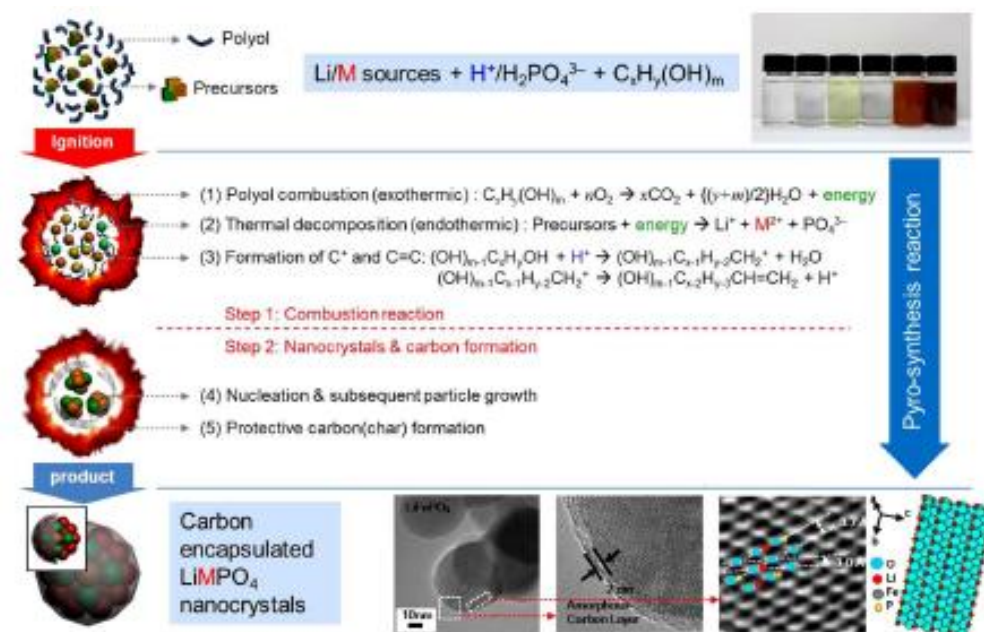

Figure 1. Rapid pyro-synthesis mechanism that explains typical production of carbon-encapsulated nanoparticles. The combustion of polyol with oxygen provides thermochemical energy for the pyrolytic decomposition of the precursors to finally yield nanoparticles under oxygen-limited condition, during which the rate of pyrolysis is much faster than the diffusion of oxygen.

# Amino-Silica Modified Nafion Membrane for Vanadium Redox Flow Battery

Chien-Hong Lin, Heng-Wei Chiang, Chao-Yen Kuo  
*Chemistry Division, Institute of Nuclear Energy Research, Longtan, Taiwan*  
*E-mail address: chlin0805@iner.gov.tw (C.-H. Lin).*

A hybrid membrane of Nafion/amino-silica (amino-SiO<sub>2</sub>) for vanadium redox flow battery (VRB) systems is prepared via the sol-gel method to improve the selectivity of the Nafion membrane, to reduce the crossover of vanadium ions, and to decrease water transfer across the membranes. The sulfonated pores of the pristine Nafion membrane are filled with amino-SiO<sub>2</sub> nanoparticles localized by electrostatic interaction. The permeability of vanadium ions through the Nafion/amino-SiO<sub>2</sub> hybrid membrane is determined by electrometric titration. The results indicate the crossover of vanadium ions through the hybrid membrane is 26.8% of the pristine Nafion membrane. The presence of amino-SiO<sub>2</sub> in the hybrid membrane is verified by X-ray photoelectron spectroscopy (XPS). Nafion/amino-SiO<sub>2</sub> hybrid membrane exhibits through plane conductivity about the same as the pristine Nafion membrane. The ion exchange capacity (IEC) of the hybrid membrane is 9.4% higher than that of the pristine Nafion membrane. In addition, Nafion/amino-SiO<sub>2</sub> hybrid membrane exhibits a higher coulombic efficiency (CE), voltage efficiency (VE), and energy efficiency (EE) over a range of current densities from 20 to 80 mA cm<sup>-2</sup>. The performance of VRB with Nafion/amino-SiO<sub>2</sub> hybrid membrane varies little around a charge-discharge current density of 80 mA cm<sup>-2</sup> for 150 cycles. Thus, the Nafion/amino-SiO<sub>2</sub> hybrid membrane can suppress the vanadium ions crossover in VRB.

# Electrochemical shape transformation of Pt nanocrystals with high-index facets

Na Tian\*, Jia-Huan Du, Shi-Gang Sun\*

College of Chemistry and Chemical Engineering and School of Energy Research, Xiamen University, Xiamen, 361005, China

\*e-mail address: tnsd@xmu.edu.cn, sgsun@xmu.edu.cn

To observe shape evolution of nanoparticles is helpful for shape-controlled synthesis of nanocrystals and understanding growth mechanism of the nanocrystals. A variety of growth conditions can influence the final shapes or surface structure of the nanocrystals. Previously, we developed an electrochemical square-wave potential (SWP) method to synthesize Pt-group metal nanocrystals with high-index facets, and found that surface structures can be tuned by the electrode potentials. The upper ( $E_U$ ) potential controls the oxygen species adsorption that can induce the formation of high-index facets, and etching Pt surface atoms. The lower ( $E_L$ ) potential enables the desorption of oxygen species, and mediates the growth of nanocrystals. The final surface structure of the obtained nanocrystals is the balance of these interactions.

As for Pt nanocrystals, we observed previously the shape evolution from  $\{hk0\}$ -faceted tetrahexahedron (THH) to  $\{hkl\}$ -faceted hexoctahedron (HOH) and finally to  $\{hkk\}$ -faceted trapezohedron (TPH) by increasing the  $E_U$  or  $E_L$  of SWP, if these nanocrystals directly grow from  $H_2PtCl_6$  plating solution [1]. Here, we found that the growth habits of Pt nanocrystals depend on starting materials. If preformed THH Pt nanocrystals are further subjected to the SWP treatment, they are not converted into HOH as expected, but into truncated ditetragonal nanoprisms (DTPs), as shown in Fig. 1. Both THH and DTP are enclosed by  $\{hk0\}$  facets, but crystal symmetries are different. The former has 24 facets, while the latter has 12 facets. The relationship between them is like that between octahedron and tetrahedron. Clearly, DTP has short edge length totally. This shape transformation occurs through elongation of tetragonal pyramid, resulting in the gradual disappearance of two facets. The driving force of this shape transformation may be attributed to reduce the high energy vertices at pyramid and cube. The study provides a new insight into growth habits of Pt nanocrystals under electrochemical conditions, and will contribute to surface structure controls of Pt nanocrystals.

Fig.1 SEM images of Pt tetrahexahedral nanocrystals (a) and truncated ditetragonal nanoprisms (b).

Redox flow batteries (RFBs), one of the promising candidates for energy storage system (ESS), require two separated and dissolved redox couples with standard reduction potential difference. Among them, vanadium redox flow battery (VRFB) has an advantage of low cross-contamination and long lifetime. However, sluggish cathode reaction ( $\text{VO}^{2+}/\text{VO}_2^+$ ) activity lowers the efficiencies of VRFB; thus, using catalysts in the cathode is essential for improving VRFB performance. Herein, we use new catalysts including large pore sized mesocellular carbon foam (MSU-F-C and Pt/MSU-F-C) to enhance the slow cathode reaction. Compared to materials including commercial carbon black (Vulcan XC-72 and Pt/Vulcan XC-72), MSU-F-C-based catalysts show higher energy efficiency, lower cathode overpotential, and lower internal resistance in single cell tests. These improved results are due to mostly of MSU-F-C having high surface area, large opened mesopores, and large ratio of hydroxyl groups which are active sites for  $\text{VO}^{2+}/\text{VO}_2^+$  redox reaction, and partly of Pt nanoparticles supported on the MSU-F-C.

# Advanced Anode Material with Bubble-Nanorod-Structured Metal Oxide-Carbon Composite Nanofibers

Jung Sang Cho, Young Jun Hong, and Yun Chan Kang

Department of Materials Science and Engineering, Korea University, Anam-Dong, Seongbuk-Gu, Seoul 136-713, Republic of Korea

jjj777@snu.ac.kr

A novel structure denoted as a “bubble–nanorod composite” is synthesized by introducing the Kirkendall effect into the electrospinning method. Bubble–nanorod-structured metal oxide–C composite nanofibers, which are composed of nanosized hollow metal oxide spheres uniformly dispersed in an amorphous carbon matrix, are synthesized. The post-treatment of the electrospun precursor nanofibers at 500 °C under 10% H<sub>2</sub>/Ar mixture gas atmosphere produces metal–carbon composite nanofibers. The post-treatment of the metal–carbon composite nanofibers at 300 °C under air atmosphere produces the bubble–nanorod-structured metal oxide–C composite nanofibers. The solid metal nanocrystals formed by the reduction are converted into hollow metal oxide nanospheres during the further heating process by the well-known Kirkendall diffusion process. The discharge capacities of the bubble–nanorod-structured Fe<sub>2</sub>O<sub>3</sub>–C composite nanofibers and hollow bare Fe<sub>2</sub>O<sub>3</sub> nanofibers for the 300<sup>th</sup> cycles at a current density of 1.0 A g<sup>−1</sup> are 812 and 285 mA h g<sup>−1</sup>, respectively, and their capacity retentions measured from the second cycle are 84 and 24 %, respectively. The hollow nanospheres accommodate the volume change that occurs during cycling. The unique structure of the bubble–nanorod-structured Fe<sub>2</sub>O<sub>3</sub>–C composite nanofibers results in their superior electrochemical properties by improving the structural stability during long-term cycling.

Figure 1. Formation mechanism of bubble-nanorod-structured Fe<sub>2</sub>O<sub>3</sub>-C composite nanofiber by Kirkendall-type diffusion.

Room-temperature ionic liquids (RTILs), which are liquid salts consisting only of cation and anion, fascinate many researchers in various fields because of their unique physicochemical properties. Among them, negligible vapor pressure of RTILs is one of the most important features for the researches that use RTILs under vacuum conditions. Our research group developed several new technologies by combining RTIL with vacuum technology, i.e., electron microscope [1]. In the investigations, we have established a completely new method to fabricate micro/nano-sized polymer structures by irradiating focused ion beam onto a polymerizable RTIL layer [2]. This technique can build various 3D polymer structures with complicated shapes by simple raster scanning irradiation. In this study, in order to extend our previous method, we employed an electron beam (EB) writing system for the micro/nano fabrications of polymer and metal structures from RTILs.

The fabrications of 3D polymer structures from 1-Allyl-3-ethylimidazolium bis(trifluoromethanesulfonyl)amide ([AllylEtIm][Tf<sub>2</sub>N]) were demonstrated in the form of drawing some images and characters. Figure 1 shows SEM images of the polymers deposited by EB irradiation onto the [AllylEtIm][Tf<sub>2</sub>N] layer that was spun on a Si substrate. The fine structures were obtained according to the irradiation design with a uniform thickness. One of the important points for our present technique is that we can make any shapes of deposits precisely by a single raster writing of images. Even if the total area exceeds 50  $\mu\text{m}^2$ , the obtained structure had a resolution of several tens of nanometers.

In order to establish the fabrication method for silver structures, we used an aliphatic type of RTIL; trimethyl-propylammonium bis(trifluoromethanesulfonyl)amide ([N<sub>1,1,1,3</sub>][Tf<sub>2</sub>N]) which contained 390 mM Ag[Tf<sub>2</sub>N]. Figure 2 shows the SEM image of the obtained silver structures. The images reveal that the reduction reaction of silver ions occurred selectively in the part where electron beam was irradiated and this technique can fabricate silver structures having desired shapes with a high resolution. More detailed information about each fabrication method will be given in our presentation.

# Electrochemical Reaction of Single Nanoparticle

Shuo Liu, Li Liu, Na Tian\*, Zhi-You Zhou, Shi-Gang Sun\*

College of Chemistry and Chemical Engineering and School of Energy Research, Xiamen University, Xiamen, 361005, China

\*e-mail address: [tnsd@xmu.edu.cn](mailto:tnsd@xmu.edu.cn); [sgsun@xmu.edu.cn](mailto:sgsun@xmu.edu.cn)

Metal nanoparticles (NPs) find widespread application due to their unique physical and chemical properties. NPs have generated considerable interest in catalysis<sup>1</sup> and electrocatalysis<sup>2</sup>, where they provide a high surface area to mass ratio and can be tailored to promote particular reaction pathways. Significant research efforts have devoted to a definitive understanding of the effect of shape and size of NP properties. The activity of NPs can be analyzed especially well using electrochemistry, which probes interfacial chemistry directly. Electrochemical techniques are especially interesting, particularly when electrochemical characteristics can be related directly to other properties of the NPs. The challenge of ultimately measuring the electrochemical behavior of individual NPs is leading to imaginative experiments that have an impact on electrochemistry in general, as well as broader surface and colloid science.

Although the electrochemical properties of a single crystal nanoparticle have been previously studied by visualizing at ultramicroelectrode<sup>3</sup>, the current is randomness and may come from several nanoparticles impacted electrode. Herein, we developed a new method to place a nanocrystal in a marked hole and can find it with microscope easily. The current of the

nanocrystal was determined by using a scanning electrochemical cell microscopy (SECCM)<sup>4</sup>. As observed in Fig.1, the current of double-layer recorded on the single nanocrystal in 0.1M H<sub>2</sub>SO<sub>4</sub> is similar with that on the hole. However, the hydrogen evolution current on the single nanocrystal is much larger than that on the hole. It is clear that the single nanocrystal is contributed to the increased current. The results demonstrated that it is electrically conductive between the particle and substrate and our new method is effective and practical.

The developed method has thrown a new insight into study electrochemical reaction of a single nanocrystal and even a crystal plane on it in combination with STM.

Fig 1. The SEM of the single particle (a) and blank hole (b). The current of them (c,d) in 0.1M H<sub>2</sub>SO<sub>4</sub>. Scan rate: 100 mV·s<sup>-1</sup>. The single particle is marked with a white circle.

Brussels, Belgium

mesfin.haile.mamme@vub.ac.be

The early stage of Electrochemical nucleation and growth process is one of the most important and interesting phenomena in nanoparticle electrodeposition. However, for many systems the process is not fully understood. In this work, we introduce a new modeling approach to study the growth of single hemispherical nucleus: Multi-Ion Transport and Reaction Model (MITReM) [1]. This approach takes into account the transport driven by diffusion and migration of all species in the electrolyte together with the electrochemical reactions at the electrode boundary. The Finite Element Method (FEM) is used to solve the balance equations for the concentration of all the active species and the electrolyte potential. In this work, we consider silver deposition in acetonitrile solution with 0.1M LiClO<sub>4</sub> as a supporting electrolyte. The simulation results confirm that, the initial stage of growth of a 10 nm single hemispherical silver nucleus always starts under kinetic control, regardless of concentration and overpotential. The reason is that, initially, the nucleus size is so small that diffusion is large enough. Secondly, it is noted that the growth of a single hemispherical silver nucleus will always show a transition from kinetic control to diffusion control. The time of transition depends on the imposed concentration and overpotential. To our knowledge, these combined phenomena have not yet been reported in other numerical approaches. In addition, the simulations clearly show that the deposition time and the rate of growth is easily affected by the imposed concentration and overpotential, as it has been proven experimentally in countless occasions. Furthermore, the simulation definitely shown the effect of nucleus size (10 nm, 20 nm, 30 nm and 50 nm) on the growth process (Figure 1(a) and (b)).

Figure 1. The current transient and the radius evolution of the hemispherical silver nucleus of different nucleus size (10 nm, 20 nm, 30 nm and 50 nm) at -200 mV (a) and (b) respectively. The solution contains 1mM of Ag<sup>+</sup> in acetonitrile solution with 1M LiClO<sub>4</sub> electrolyte.

# Activity and Stability of Pt Clusters supported on Au(111) for Electro-oxidation of Formic Acid

Hongjiao Li<sup>1</sup>, Yunchang Liang<sup>2,3</sup>, Wenbo Ju<sup>2,3</sup>, Marian D. Rötzer<sup>1</sup>, Florian F. Schweinberger<sup>1</sup>, Ulrich Stimming<sup>2</sup>, Ueli Heiz<sup>1</sup>, Oliver Schneider<sup>2</sup>

<sup>1</sup>Lehrstuhl für Physikalische Chemie, Catalysis Research Center and Chemistry Department, Technische Universität München, Lichtenbergstr. 4, 85748 Garching, Germany; <sup>2</sup>Institut für Informatik VI, Technische Universität München Schleißheimerstr. 90a, 85748 Garching Germany <sup>3</sup>Physik-Department, James-Frank-Str.1, Technische Universität München  
h.li@tum.de, oliver\_m.schneider@tum.de

Pure platinum as an electrocatalyst for the oxidation of formic acid is well known to be poisoned by CO, generated as surface intermediate in the indirect oxidation pathway<sup>1</sup>. Previous reports on Pt-Au alloys<sup>2</sup>, Pt decorated Au nanoparticles<sup>3</sup> and Pt-Au core-shell nanoparticles<sup>4</sup> demonstrated both advanced activity and stability compared to Pt. Despite these achievements, there is still a strong need for further study of the catalysis at the bimetallic systems and especially for exploring the underlying reaction mechanism.

In this work, unselected Pt<sub>n</sub> (n>35 atoms) clusters generated in a laser-ablation cluster source with an average surface area of 0.92 nm<sup>2</sup> per cluster were deposited on Au(111) under soft-landing conditions in an ultra-high vacuum (UHV) system<sup>5,6</sup>. As this technique provides a uniform distribution and an accurate size-control of the Pt clusters, the role of Au(111) on the oxidation of formic acid can be studied by varying the surface coverage of deposited Pt. For a sample with a high coverage of 1.16 clusters per nm<sup>2</sup>, the scanning tunneling microscopy (STM) image in Figure 1a elucidates the surface morphology. The image confirms that the landed clusters are around 1 nm high and form a uniform deposit. The electrochemical performance tests shows that the as prepared Pt<sub>n>35</sub>@Au(111) is much more active than Pt and further increases upon cycling. STM imaging of the sample after 50 cycles indicated no obvious agglomeration of the Pt particles. The enhanced activity and stability of our Pt<sub>n>35</sub>@Au(111) is attributed to the active boundaries of the Pt clusters and the Au substrate. With decreasing Pt coverage, the potential of the main oxidation peak shifts to higher values. The results clearly indicated that Au plays an important role in the Pt-Au bimetallic catalyst for electro-oxidation of formic acid.

Figure 1. (a) STM image of Pt<sub>n>35</sub> clusters on Au(111). Inset: Height profile along blue line. (b) Cyclic voltammetry of two catalyst materials in 0.1 M HClO<sub>4</sub> + 0.5 M HCOOH at 50 mV s<sup>-1</sup>. The current is normalized to the actual Pt area as determined from H<sub>UPD</sub>.

# Nanostructured Monolayers on Carbon Substrates.

Yann R. Leroux, Philippe Hapiot

*Institut des Sciences Chimiques de Rennes, CNRS, Université de Rennes I  
263, avenue du Général Leclerc, Campus de Beaulieu, Bat 10C, Rennes, 35042 France  
yann.leroux@univ-rennes1.fr*

The electro-generation of aryl radicals from protected aryl diazonium salts combined with protection-deprotection steps<sup>1</sup> was evaluated to design functional monolayers on carbon substrates with a well-controlled organization of the modifier at the molecular scale. The influence of the size of different silyl protecting groups on resulting covalently bounded films were investigated. Three different protecting groups were considered: trimethylsilyl (TMS), triethylsilyl (TES) and tri(isopropyl)silyl (TIPS). When the active function was introduced on para position of the aryl ring, a robust ethynylaryl monolayer is obtained after deprotection whatever the substituent. Electrochemical and structural analyses show that the organization of the attached monolayer is totally governed by the size of the protecting group. Properties of the monolayer (charge transfer, permeation of molecules through the layer, density of functional groups) were examined in combination of the performances for post-functionalization taken an alkyl-ferrocene derivative as an example of immobilized species. As a remarkable feature, all layers present large density of active alkyne terminations that remain totally available for further “click chemistry” coupling.<sup>2</sup>

Organic molecular cage salts containing protonated secondary amine groups show promise as proton conducting electrolytes due to their high water uptake, intrinsic porosity and appreciable ionic conductivity. Herein we report the proton conductivity of reduced amine cage salts with conductivities in the range  $10^{-3}$ – $10^{-2}$  S cm $^{-1}$ , at temperatures up to 80°C. These cages are formed from reversible imine bond formation and packing of discrete, rigid cage molecules results in a defined microporous structure <sup>[1, 2]</sup>. Proton conductivity was investigated using the 2-probe AC method of impedance spectroscopy under varying humidity and temperature for various cage systems. The determined activation energies of ca. 0.3 eV indicate a mixed Grotthuss and vehicular method of proton transport and suggest high intrinsic proton transport for some cage materials (Figure 1) <sup>[3]</sup>. Proton transference number was measured to be 0.71 via chronoamperometry using an H-cell containing equimolar concentrations of acidic and basic media, indicated that the counter ion was not the major charge carrying species. Comprehensive simulation studies and structural characterisation using powder XRD, solid state NMR and water uptake measurements suggests that water molecules form clusters within the voids of the charged cage cations and as a result, become polarised which facilitates proton transport. Both molecular dynamic simulation and transference number studies suggest that the anionic moieties investigated (for example Cl $^{-}$  and SO $_4^{2-}$ ) are too large to be mobile and remain fixed around each cage cation.

Figure 1: Arrhenius plot showing conductivity range with temperature for reduced cage 1 chloride salt (RCC1.Cl, shown inset). The activation energy indicates a mixed mechanism of proton transport.

Development of materials with outstanding energy capacity and structural durability is especially of paramount importance in Li-ion batteries. The bi-functional properties have been seriously challenged to high Ni cathodes via unfavorable electrochemical and thermal instability when exposed to liquid organic-phase electrolytes or under ambient environment above room temperature.

Conformal ultrathin Al<sub>2</sub>O<sub>3</sub> coating by atomic layer deposition (ALD) has been mostly employed to enhance the electrochemical stability of the cathodes. However, atomistic understanding of thermal stability issue still remains.

In this presentation, we extensively utilize first principles density functional theory (DFT) calculations to identify the thermal stabilities of Al<sub>2</sub>O<sub>3</sub> coated LiNiO<sub>2</sub> (LNO) (012) surface. First, the interface structures between LNO and varying Al<sub>2</sub>O<sub>3</sub> coating layers increased from 0.20 nm ~ 0.88 nm were calculated. We identify that phase transformation of Al<sub>2</sub>O<sub>3</sub> from ordered into amorphous structure as the thickness reach about 0.88 nm, at which the cathode shows exceptional thermal durability with suppressed oxygen evolution. Second, thermal stability of LNO (012) facet with and without Al<sub>2</sub>O<sub>3</sub> coating layer are predicted at higher than ambient temperature (T = 400 K) using ab-initio molecular dynamics (AIMD). Finally, by calculating electron density distributions we characterize chemical bonding natures of Li-O and Al-O to understand underlying mechanism providing such high thermal stability.

# GO/rGO Microelectrode Arrays with Adjustable Electrochemical Activity and Biocompatibility for Highly Sensitive Detection of Hydrogen Peroxide Released by Living Cells

Aiping Liu, Ming Zhao, Panju Xu, Guodong Qian

Center for Optoelectronics Materials and Devices, Zhejiang Sci-Tech University  
Hangzhou, Zhejiang Province 310018, China  
liuaiping1979@gmail.com

Cell secretions detection is of very importance in disease diagnosis and precaution. Especially, hydrogen peroxide ( $\text{H}_2\text{O}_2$ ), as the stable and common reactive oxygen species (ROS) among intracellular signaling molecules is being proved to play a vital role in physiological signaling pathways of healthy cells through mainly regulating DNA damage, cell apoptosis and protein synthesis. Electrochemical biosensors based on noble metals have been developed for  $\text{H}_2\text{O}_2$  detection due to their rapid response, good simplicity and sensitivity [1]. However, it is almost inevitable that the release of metal ions and endocytosis of nanoparticles will affect the cell metabolism in living systems.

In this paper, a catalyst-free and multi-functional graphene-based microelectrode array (MEA) is fabricated on arbitrary substrates by an electrochemistry-assisted microstructuring process [2]. The dimension of special-shaped rGO microarrays localized in an insulating GO matrix is effectively adjusted by changing GO reduction time without multi-mask patterning. When the pheochromocytoma cells (PC12) are seeded on the GO/rGO MEA, PC12 prefer to migrate and grow on the GO surfaces, exactly distribute along the interface of GO and rGO with filopodia fixed on rGO surface, which favors the highly sensitive detection of  $\text{H}_2\text{O}_2$  released by the stimulated living cells at the nanomolar level. The present MEA would have a potential application in next generation electronic and electrochemical devices.

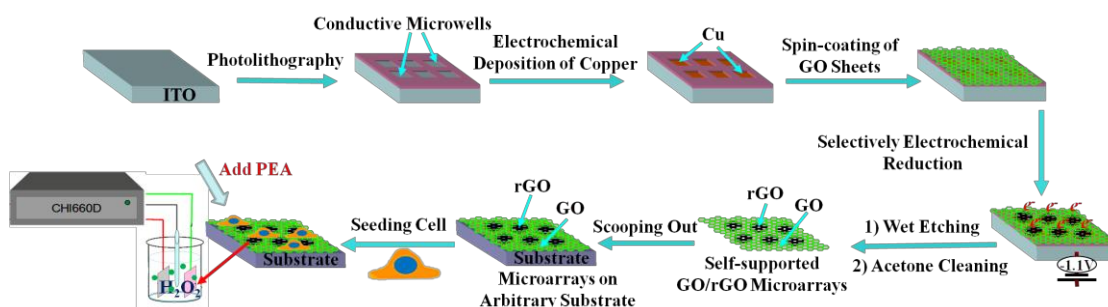

Figure 1. Schematic illustration of GO/rGO MEA fabrication of  $\text{H}_2\text{O}_2$  detection released by living cell.

When spun directly and continuously from gas phase as an aerogel, carbon nanotubes (CNTs) are able to form high-performance fibers [1]. These macrostructures can be successfully applied as wires in electrical transformers, fillers for composites with superior erosive wear resistance and materials for electromagnetic shielding and electrostatic dissipation applications. The properties of CNT fibers can be further enhanced by covering them with conjugated polymers (CPs). Highly conductive CPs are expected to enhance the direct charge transfer with electron hopping effects on intertube conductivity, leading to further decrease in resistivity of CNT material [2].

Poly(3,4-ethylenedioxythiophene), PEDOT, exhibits superior chemical and electrochemical stability as compared to other CPs. When electrodeposited on the surface of horizontally aligned carbon nanotube (HA-CNT) electrode, it is able to cover the surface of each HA-CNT individually. The mechanism of the nucleation process highly depends on the reaction environment. The presence of a surfactant or non-aqueous medium favors the progressive nucleation in which the polymer growth is homogeneous over the large area of the electrode. Because of the non-uniform in respect of conductivity area of HA-CNT, the application of overpotential is necessary to generate radical cations and cause relatively fast growth of polymer layer [3].

# Insight into the effect of oxygen vacancy concentration on the catalytic performance of MnO<sub>2</sub>

Li Li,\* Yao Nie, Siguo Chen, Wei Ding, Xueqiang Qi, Feng Shi, Zidong Wei\*

Chongqing Key Laboratory of Chemical Process for Clean Energy and Resource Utilization, School of Chemistry and Chemical Engineering, Chongqing University, Chongqing, 400044; China  
zdwei@cqu.edu.cn; liliracial@cqu.edu.cn

Oxygen vacancies (OVs) are important for changing the geometric and electronic structures as well as the chemical properties of MnO<sub>2</sub>. In this study, we performed a DFT+U calculation on the electronic structure and catalytic performance of a  $\beta$ -MnO<sub>2</sub> catalyst for oxygen reduction reaction (ORR) with different numbers and extents of OVs. Comparing to the experimental XRD analysis, we determined that OVs produce a new crystalline phase of  $\beta$ -MnO<sub>2</sub>. Changes in the electronic structure (Bader charges, band structure, partial density of states (PDOS), local density of states (LDOS), and frontier molecular orbital), proton insertion and oxygen adsorption in  $\beta$ -MnO<sub>2</sub> (110) were investigated as a function of the bulk OVs. The results show that a moderate concentration of bulk OVs reduced the band gap, increased the Fermi and HOMO levels of the MnO<sub>2</sub> (or MnOOH), and elongated the O-O bond of the adsorbed O<sub>2</sub> and co-adsorbed O<sub>2</sub> with H. These changes substantially increase the conductivity of MnO<sub>2</sub> for the catalysis of ORR. However, an excessively high concentration of OVs in  $\beta$ -MnO<sub>2</sub> (110) will work against the catalytic enhancement of MnO<sub>2</sub> for ORR. The DFT+U calculation reveals that a moderate concentration of OVs induced a large overlap of the surface Mn orbitals and thus introducing an extra donor level at the bottom of the conductive band (CB), which increased the conductivity of  $\beta$ -MnO<sub>2</sub> (110). Such a curvilinear change of the catalytic activity and electronic structure as a function of the oxygen vacancy concentration suggests that the  $\beta$ -MnO<sub>2</sub> with moderate concentration OVs exhibits the highest conductivity and catalytic activity for ORR. Therefore, the electronic structure and catalytic performance of  $\beta$ -MnO<sub>2</sub> can be effectively modulated by regulating the oxygen vacancy concentration.

\**emmanuel.rocce@univ-lorraine.fr*

Since several ten years, a large number of heritage collections are related to the technical and industrial field because society wishes to preserve those materials which constitute traces of our industrial development. The diagnosis of the conservation state and the choice of the restoration treatment are important questions, that have to be solved by curators to avoid expensive restoration works on numerous objects or important buildings as U4 blast furnace in Uckange in France.

Previous studies [1] have demonstrated that the electrochemical properties of some iron(III) oxyhydroxide phases constituting the rust layers play an important role in the corrosion processes during wet and dry periods, and can increase the corrosion rate of the underlying metal.

The purpose of this study is to functionalize the surface of iron oxyhydroxide constituting the rust layers to freeze or block the electrochemical activity of these complex systems in order to lower the degradation rate of structures, without applying thick organic coatings as paints or varnishes.

The surface functionalization is based on a dip treatment in linear aliphatic carboxylic acid solutions [2] to form by a self-organization process a nanometric layer of iron carboxylate, constituted by the “ferric wheel” cluster.

The electrochemical activity of the functionalized oxyhydroxide iron compounds was characterized by cyclic voltamperometry in a carbon paste electrode, and the behavior of the whole “metal/rust layer” system after functionalization was described by recording electrochemical impedance spectroscopy in aqueous corrosive media in function of immersion time.

In-situ x-ray absorbance spectroscopy (XAS) measurements [3] allow confirming the formation of the “ferric wheel” cluster from the iron oxyhydroxide during the treatment, with a chemical formulae  $[\text{Fe}_3\text{O}(\text{C}_n\text{H}_{2n+1}\text{O}_2)_6(\text{H}_2\text{O})_3]^+$  ( $n$  = carbon number of aliphatic chain). So, the EIS analysis coupled with the analysis of the oxides surfaces (SEM, X-ray diffraction, Raman spectroscopy) show that the application of the functionalization treatment has a positive effect on both the dissolution of iron species, then their chemical diffusion in the pores network of the rust layer, and the electrical conductivity of the oxide system. So, the electrochemical reactivity of the iron oxide phases is drastically reduced.

From those experiments, it turns out that these functionalization solutions represent an interesting alternative of new environmentally safe treatments for corroded steels as iron artefacts.

Fig 1 : Principle of functionalization of oxyhydroxide iron layer – From the “Ferric wheel” to a functionalized surface

## Abstract:

In this study, a new class of polymerizable ionic liquids were synthesized and modified upon conductive surfaces to enhance the sensitivity and/or selectivity of the electrodes, which were used for electroanalytical and electrochromic application. At suitable conditions, the poly-ionic liquids were liquid and soluble in some organic solvents.

Ionic liquids (ILs) have shown the advantages on electroanalysis if they can be modified on electrode surface. Electropolymerization might be a good approach for the modification of ILs on conductive surface. Various carbazole-based ILs (Figure 1) were synthesized in this study and they were electropolymerized on indium tin oxide (ITO) electrodes by cyclic voltammetry in ILs BMP-TFSI, Bu<sub>3</sub>MeN-TFSI and etc., as well as in conventional solvents (Acetonitrile, methanol) <sup>[1]</sup>. Electrochemical oxidation of the carbazole pendant units affords a conjugated polymer network (CPN) film of polycarbazole and the polymer is expected to have good conductivity on the conducting surface<sup>[2]</sup>. The electrodes with electropolymerized ILs will be used for the determination of various bio-molecules, such as uric acid (UA) and also in the field of electrochromic devices.

jaeyoung@gist.ac.kr

Carbon dioxide (CO<sub>2</sub>) emission from the fuel combustion and other human activities are of great interest due to its adverse effects on climatic change and ecosystem. In terms of reducing atmospheric CO<sub>2</sub>, the CO<sub>2</sub> utilization for synthesizing useful chemicals attracts a significant attention as an alternative method compared to capture and sequestration techniques [1]. In particular, electrochemical reduction of CO<sub>2</sub> has been studied using metal oxide catalysts which are reported as the superior catalysts very recently [2-3]. Furthermore, from our recent study, it was demonstrated that stannic oxide (SnO<sub>2</sub>) can efficiently catalyze formate production (HCOO<sup>-</sup>) from CO<sub>2</sub> and oxygen-evacuated cuprous oxide (Cu<sub>2</sub>O) enhance the product selectivity towards ethylene from CO<sub>2</sub> at lower overpotential [4-5]. In this report, we study the electrochemical reduction of carbonate species on the both two types of metal oxide catalysts under the various pH conditions. The electrolyte pH is an important indicator regarding the CO<sub>2</sub> equilibria in aqueous system [6]. With this recognition, considering the distribution of dissolved CO<sub>2</sub>, bicarbonate (HCO<sub>3</sub><sup>-</sup>) and carbonate (CO<sub>3</sub><sup>2-</sup>) which are functioning as a CO<sub>2</sub> reservoir, catalytic activity, selectivity and stability for CO<sub>2</sub> electroreduction are evaluated using SnO<sub>2</sub> and Cu<sub>2</sub>O electrode.

# A multi-scale model to account for the electrochemical response of the oxygen reduction reaction on highly active graphene nanosheets in alkaline conditions

Guadalupe Ramos-Sanchez<sup>a</sup>, Jorge Vazquez-Arenas<sup>b</sup> and Alejandro A. Franco<sup>c</sup>

Departamento de Química, Universidad Autónoma Metropolitana, Av. San Rafael Atlixco No. 186 Col. Vicentina México, D.F., 09340 México

<sup>a</sup>gramossa@conacyt.mx

<sup>b</sup>jorge\_gva@hotmail.com

<sup>c</sup> Laboratoire de Réactivité et Chimie des Solides (LRCS) - Université de Picardie Jules Verne & CNRS, UMR 7314 – 33 rue Saint Leu, 80039 Amiens Cedex, France

A multi-scale modeling framework is used to describe polarization curves collected for the oxygen reduction reaction (ORR) performed on highly active graphene nanosheets in alkaline conditions. Density functional theory (DFT), and electrode kinetics with transport phenomena are respectively utilized to compute the inputs at the different scales. The framework extracts *ab initio* information of the chemical contributions to the activation energies for the elementary reaction steps involving the multiple adspecies generated within the mechanism at the atomic level. This information is subsequently connected with a mesoscale-level Mean Field model, which integrates the current density of the elementary steps along with the chemical data obtained from quantum mechanics.<sup>1</sup> In order to enhance the influence of the catalyst properties on the ORR mechanism, a sensitivity analysis is conducted to compare the multi-scale and single mesoscale-level models. Likewise, the electrochemical parameters are determined by fitting the experimental data to each model, to determine the deviations existing in sole scale models (e.g. mesoscale, macroscopic). The surface coverage on the cathode material and the catalytic nitrogen bonding (e.g. pyridinic, pyrrolic, and quaternary) are also evaluated to determine their influence upon the activation energy of the elementary steps.

ORR polarization curves (900 RPM) recorded on Pt/C and Graphene nanosheets in O<sub>2</sub>-saturated KOH electrolytes.

bchan@yonsei.ac.kr

Using density functional theory (DFT) calculations and statistical formalisms we rationally design metallic nanocatalyst with ternary transition metals for oxygen reduction reaction (ORR) in fuel cell application. We surround binary core-shell nanoparticles with a Pt skin layer. To overcome surface segregation problem of the core 3-d transition metal we identified a binary alloy  $\text{Cu}_{0.76}\text{Ni}_{0.24}$ , having strongly attractive atomic interactions by computationally screening 158 different alloy configurations using energy convex hull theory. The Pt-skin- $\text{Cu}_{0.76}\text{Ni}_{0.24}$  nanoparticle shows better electrochemical stability and higher ORR activity than bulk Pt at approximately 3 nm. We propose that underlying mechanisms of the results are originated from favorable compressive strain on Pt for ORR catalysis and atomic interactions between the nanoparticle shells for electrochemical stability. Our results will contribute to accurate identification and innovative design of promising nanomaterials for renewable energy systems.

We also demonstrate that Cu@N-C catalysts are promising catalysts with enhanced ORR activity and durability by experiments and computations. The active Cu@N-C catalyst is synthesized by  $\text{CO}_2$  treatment. Carbon dioxide gas at high temperature induces the dramatically enhanced ORR activity by the oxidation of the surface carbon atoms. We expect that  $\text{CO}_2$  treatment could be employed in a variety of carbon encapsulation structures such as metal@N-C, metal carbide@N-C, metal oxide@N-C to control the thickness of carbon layers.

These two results are outstanding examples showing how to screen desired materials with more than single properties using combined multi-scale computations, which are often validated by experimental measurements.

# Boosting Lithium Air Batteries from a Multiscale Modeling Approach

[yin.yinghui@u-picardie.fr](mailto:yin.yinghui@u-picardie.fr)

Li Air Batteries (LABs) can theoretically provide a capacity significantly higher than conventional Lithium Ion Batteries<sup>1</sup>. However, there are still a significant amount of challenges in the way of bringing LABs to practicality. For instance, resulted from its insulating and insoluble nature, the discharge product  $\text{Li}_2\text{O}_2$  would bring in hindrance to charge transfer as well as mass transport limitations in the cathode by insulator film formation and pore clogging.

It is reported that the passivation of carbon surface could be delayed when high donor number solvents were employed, which give rise to the formation of toroidal  $\text{Li}_2\text{O}_2$  through a solution phase reaction mechanism.<sup>2</sup> But the origin of this mechanism, whether from the existence of water<sup>3</sup> or the solubility of  $\text{Li}^+\text{-O}_2^-$  pair<sup>2</sup>, is still under debating. Besides, the pore clogging problem stays unsolved and even becomes more serious at high rate discharging conditions, leading to inactivation of effective surface inside the choked pore. Hence, to improve the performance of LABs, it is illuminating to bypass the above inherent limitations by designing and optimizing the cathode architecture.

Following a multiscale computational modeling approach being developed by us,<sup>4</sup> here we extend our previous discharge model for  $\text{Li-O}_2$  batteries<sup>5,6</sup> in order to investigate the influence of different innovative cathode architectures onto the overall cell performance. Architectures explored include porosity gradients along the cathode thickness as well as implanting pipe-like channels with different volume densities within cathode, aiming to facilitate the oxygen transport especially at high discharge rates. Furthermore, by using three-dimensional mesoscale simulations at the pore level<sup>7</sup>, the competition of thin-film mechanism and solution phase mechanism are studied to elucidate the effects of the local cathode microstructure on the details of the reaction mechanisms.

The modeling results are discussed in comparison with state-of the-art data, and allow establishing a single comprehensive theoretical framework explaining multiple experimental observations. Practical implications of our approach towards the design of the next generation of LABs are finally discussed.

# **Water Management in Proton Exchange Membrane Fuel Cells by Materials Design and Engineering**

Trung Van Nguyen

*University of Kansas*

*Department of Chemical & Petroleum Engineering, Lawrence, Kansas, USA*

*cptvn@ku.edu*

## **Abstract**

Proton-exchange-membrane fuel cells (PEMFCs) depend on proper water management to obtain high power density and energy efficiency. Proper water management also plays a major role in the durability of the membrane-electrode assemblies. Traditionally, water management has been addressed by system design and engineering. That is, by adding auxiliary systems to the basic fuel cell system to provide humidification to the anode and to remove water from the cathode. This approach adds significant complexities and costs and reduces the overall efficiency of the PEMFC system. Development of new materials and better understanding of the functions of these materials have led to a paradigm shift as to how water management can be implemented in a PEMFC system. Theoretical calculations have shown that if materials with the right properties are used in the membrane and electrodes such that zero-net-water transport across the membrane could be achieved, then water management in a PEMFC system could be attained with no or minimal external-water requirement. If this objective could be achieved, the PEM fuel cell system and its operation would be greatly simplified, and its cost would be greatly reduced. This presentation will discuss some of the approaches that could be used to achieve the zero-net-water transport condition across the membrane.

*Daniel.Brandell@kemi.uu.se*

Battery modelling is a key technique for the understanding of electrochemical processes in the cell in context of the inherent morphological conditions and different loss mechanisms. At the same time, electrochemical impedance spectroscopy (EIS) is as a fast, non-destructive and reliable method to determine battery state of charge (SoC) [1,2]. Impedance studies are known to provide several important parameters such as charge-transfer resistance, double-layer capacitance, etc. These parameters are seminal to: (1) derive information on the optimum utilization of the storage batteries; (2) understand the modes of the cell failures; and (3) determine SoC [3]. Finite Element Methodology (FEM) studies have proved very fruitful for Li-ion battery (LiB) modelling in recent years. However, these studies have generally not yet been used for exploring the different factors affecting the LiB SoC. This work attempts to utilize the possibilities of correlating cell impedance with the FEM modelling for SoC prediction. The objective is to extract electrical parameters which vary continuously as a function of the battery SoC from the impedance spectra [4]. In short, the following impedance components will be examined computationally and experimentally as functions of the SoC: a) Ohmic resistance of the battery ( $R_{\Omega}$ ); b) constant phase element (CPE) corresponding to the high frequency capacitive semicircle; c) parallel charge-transfer resistance ( $R_{ct}$ ); d) CPE corresponding to the low-frequency capacitive semicircle; e) frequency maximum and corresponding real as well as imaginary components of the impedance spectra; f) phase angle at several frequencies.

The increasing interest in miniaturized analytical systems involving small-volume samples induces to the development of “Nanoelectrochemistry”, which combines the advantages of nanotechnology and electroanalysis. As a result, several research works attempted to miniaturize complete electrochemical cells. This is an important challenge because of the necessity to minimize the sample volume when dealing with toxic waste, or precious body fluids, expensive reagents, or to precisely trap single cells. Microwells with recessed ring nanoelectrodes are a novel kind of electrochemical devices that attract big attention. Similar to ultra-microelectrodes, they exhibit high current density, fast response time, reduced charging current and high signal to noise ratio. In addition, their small volumes make them well suited for the detection of low concentrations or for the analysis of individual cells. In the current study, recessed platinum ring nanoelectrodes (RNE) and disk ultramicroelectrodes (DME) (surface:  $21\ \mu\text{m}^2$  and  $64\ \mu\text{m}^2$ , respectively) into microwells (diameter:  $9\ \mu\text{m}$ , depth:  $5.2\ \mu\text{m}$ ) were realized using silicon-based technology (Figure 1). These electrochemical devices were characterized by cyclic voltammetry with different redox probes (ex. ferrocene methanol:  $\text{Fc}(\text{MeOH})$ ) using a single well or arrayed configurations, and optimised compared to COMSOL<sup>TM</sup> simulations. Steady-state sigmoidal responses were evidenced for the DME devices in agreement with theoretical studies. Similar results were obtained for the RNE ones and validated by our theoretical model (Figure 2). To check the confinement effects within microwells, devices were used in generator-collector mode. Chronoamperometry (Figure 3) was used to quantify the amplification and collection factors: around 1.3 and 0.67, respectively. All these results demonstrate that such microsystems could be effectively used for the electrochemical analysis of single cells.

Figure 1: SEM image of  $9\ \mu\text{m}$  diameter  $\text{SiO}_2$  microwell showing the bottom layer recessed DME and the middle layer RNE devices

Figure 3: Chronoamperograms for recessed disk/ring electrodes in 1 mM  $\text{Fc}(\text{MeOH})$  solution (respective electrical bias: 0.4 and 0V).

Figure 2: Comparison between simulated (solid line) and experimental (dotted line) cyclic voltammograms detected in 1 mM  $\text{Fc}(\text{MeOH})$  solutions with the platinum ring nanoelectrodes in microwells

## Solid electrolyte interphase formation in dye-sensitized solar cells: where experimental ends and modeling could start

Frédéric Sauvage\*, Miguel Flasque, Albert Nguyen Van Nhien

*Frederic.sauvage@u-picardie.fr*

Further strengthened by the recent achievement of 13 % power conversion efficiency (PCE)<sup>[1]</sup>, the credibility of DSC for day-to-day utilization has never been as unequivocal as today. Beside such a record efficiency, establishing once again its reliable place in the photovoltaic panorama, to see it a light of day successfully introduced into the market, this last phase will now depend on how to make it more stable while preserving low-cost and sufficient PCE. Towards such objectives, two approaches are actually opposed: introduction of new materials by somehow playing at the naval battle vs. understanding the high complexity of the different chemical/electrochemical interactions between the DSC components, especially under temperature and/or light stresses. By simply looking at the actual scientific production in the domain, this top-down approach is much marginalized.

For long time, dye and sealant was culprit to account for the lack of stability. For instance, it is often answered that if the electrolyte leaks at a sudden moment it is because of poor sealing or if the performance is dropping upon ageing, it stems from the dye stability. Our principal research is actually focused on better understanding the chemical/electrochemical reactions which can take place in the cell upon ageing according to IEC61646 protocol. The objectives are to gather different experimental data to propose *in fine* a realistic mechanism accounting for the performance failure at elevated temperatures, to bring a beginning of an answer to the frequent speculations raised in the literature such as on the origin of iodine consumption or on why electrolyte leaks swiftly > 60°C whereas MPN boiling point is *ca.* 165°C.

Against the general preconceived idea, we will highlight during this presentation that one of the most stable DSC constituent, TiO<sub>2</sub>, plays in reality a significant role on the electrolyte degradation<sup>[2]</sup>. For first time, we have demonstrated this latter to be responsible of (i) the formation of highly volatile compounds including gas evolution driven by the temperature and (ii) we revealed the growth of a conformal solid electrolyte interphase (SEI) layer wrapping not only TiO<sub>2</sub> but also the Pt catalyst at the counter-electrode. The chemical composition of this SEI will be described. The collateral implication of this SEI formation on both the electrolyte composition and charge transfer kinetic into the device will be discussed. This experimental observation, which will govern the device lifetime, paves the way not only to new development of more robust chemicals but also call for modeling at multiscale to offer predictive directions to help the experimentalists in the quest of highly durable dye-sensitized solar cells development and also to deepen our understanding on the impact of SEI growth versus the multifaceted device complexity in terms of mass transport into the mesopores, charge transport, dynamic of recombinations and dye regeneration.

# Catalyzing Innovation in Organic Battery Electrodes from Computational Modelling

C. Frayret\*, D. Tomerini, C. Gatti, Y. Danten

\* LRCS-CNRS UMR 7314, Université de Picardie Jules Verne, 33, Rue Saint-Leu, 80039 Amiens, France, Phone: +33(0)3.22.82.75.86, Fax: +33(0)3.22.82.75.90  
christine.frayret@u-picardie.fr

The increase in the importance of eco-friendly considerations in the field of energy supply currently motivates the need to identify new strategies for the development of alternatives to commercial inorganic lithium-ion battery. The desired emergence of sustainable technologies thus pushes research towards new directions. Electroactive organic battery electrodes (containing no scarce metal resources) continue gaining attention mainly due to their benefit in terms of environmental benignity combined with a decreased cost (along with the potential extraction from biomass). Energy efficiency will be key in the possible advent of manufacturing for such new set-ups. Taking advantage of the possible fine tuning of redox potential provided by this kind of materials, one should ideally design low-weight electrodes exhibiting high cell voltage (*i.e.* high/low redox potential for positive/negative electrodes) and being completely devoid of solubility issues. Yet, several barriers might still inhibit such objective. For instance, tackling difficulties in achieving electronic conduction in these materials still remain a major concern. Experimental sequences improve most of the time one of the required features while they may be detrimental or inactive with respect to other specifications. Moreover, they involve iterative, costly and time consuming trial and error approaches. As a complementary tool, new theoretical paradigms are likely to facilitate or accelerate the production of suited organic electrodes. Simulation can be situated directly upstream or downstream of the relevant experiments, involving investigations at various scales (*e.g.* molecular/materials modelling) and as support of the characterization methods.

First, a work of prospection and engineering can correspond to the initial and most significant milestone in designing advanced materials. The emergence of strategies for lead candidates' identification requires the establishment of property-based guidelines. Improvement of success rates for innovation therefore relies on the ability to rationally understand the quantitative structure-activity relationship. Spin density maps, electronic delocalization indices or energy stabilization decomposition, ... clearly constitute powerful local indicators that enable to distinguish molecular compounds, especially regarding their ranking in terms of electrochemical features. In particular, fine dissection of these data can give the opportunity to discover subtleties regarding the role played by each parameter within various sets of combined effects of functionalization/heteroatom substitution/nature of backbone, ... that could not be disentangled easily otherwise. Recent studies in this area outline lessons originating from the consideration of both systematic screening of existing compounds modulated through various effects and hypothetical novel candidates [1]. By exploring various invention possibilities, the ultimate goal of such investigations is to engineer a few potentially attracting new compounds.

Beyond design problematics through molecular modelling, computational studies can be beneficial as well for the direct consideration of the material (through *e.g.* periodic DFT simulation). For instance, due to the possible partial lack of accurate structural knowledge of either one or various (lithiated/delithiated) phase(s), guess of lithium positioning may become crucial to fully understand the electrochemical process [2]. In link with the peculiar difficulties arising from the large extent of relative orientation of molecules/lithium ions, the set of relevant tools for achieving this purpose can be broader than pure DFT computations and may involve multi-scale modelling. Additionally, spectroscopic simulations may eventually complement the experimental characterization and play a part in the full interpretation of the structural changes occurring during the electrochemical process.

Based on our recent theoretical studies, an overview of the potentialities of modelling approaches will be provided with a specific focus on the way to contribute to the conceptual knowledge of these compounds for paving the road towards improved organic electrode materials development.

# Electrochemistry with Nanobioconjugates and Soft Interfaces for Sensing Applications

Hye Jin Lee

*Department of Chemistry and Green-Nano Materials Research Center, Kyungpook National University,  
80 Daehakro, Buk-gu, Daegu, 702-701, Republic of Korea  
hyejinlee@knu.ac.kr*

Over the last decade, numerous efforts have been made on creating highly sensitive and selective electrochemical biosensing platforms for a wide range of biological, food and environmental science applications. In this talk, we will highlight our recent efforts on developing amperometric biosensors utilizing two distinct electrochemical interfaces: gold nanobioconjugates and soft interfaces between two immiscible electrolyte solutions. The first part of my talk includes the combined use of nanobioconjugates and surface enzyme reactions for the development of highly sensitive and selective amperometric biosensing platforms that can be usefully employed for food science and medical diagnostics. For example, a layer by layer assembly of oppositely charged Au nanocubes, polyelectrolytes and enzymes on a screen printed carbon electrode (SPCE) was developed for the selective and sensitive detection of catechol compounds in various tea samples [1]. The second part of my presentation will be on amperometric ion selective sensing platforms featuring a single micro-hole interface supported on a thin polymer substrate between water and gelified organic phases for water quality control and pharmaceutical applications. Amperometric responses upon the transfer of anticancer drug molecules [2] and Cu(II) ions [3] across the polarized microhole supported soft interface were utilized to create a selective and sensitive detection platform.

# Theoretical Study of Lithium-Sulfur Battery Cathodes

Payam Kaghazchi

*Institut für Chemie und Biochemie, Freie Universität Berlin*

*Takustr. 3, 14195 Berlin, Germany*

*payam.kaghazchi@fu-berlin.de*

In this talk, I will present our recent efforts to model Li-S battery cathodes. Theoretical studies on the electronic and atomic structure as well as Raman spectra of intermediate and final products of discharge process will be discussed. I will first present our results for intermediate  $\text{Li}_2\text{S}_x$  polysulfide species. By comparing our theoretical Raman spectra to the experimental spectra we study the mechanism of lithiation of sulfur. It is found that  $\text{Li}_2\text{S}_x$  molecules bind strongly to each other, forming crystal-like  $\text{Li}_2\text{S}_2$  structures. The crystallization is driven by strong electrostatic interactions between  $\text{Li}^{+\delta}-\text{S}^{-\delta}$  dipoles of  $\text{Li}_2\text{S}_x$  molecules. Afterwards, the interaction of  $\text{Li}_2\text{S}_x$  with graphene and the possibility of inhibiting the shuttle effect will be discussed. Finally, I will present our results for  $\text{Li}_2\text{S}$  which is the final product of lithiation of sulfur. It is found that  $\text{Li}_2\text{S}$  particles consist of  $\{111\}$  facets which are metallic at low concentrations of surface Li atoms.

# Toward efficient electrochemical conversion of CO<sub>2</sub>: catalyst design accelerated by simulation-based screening

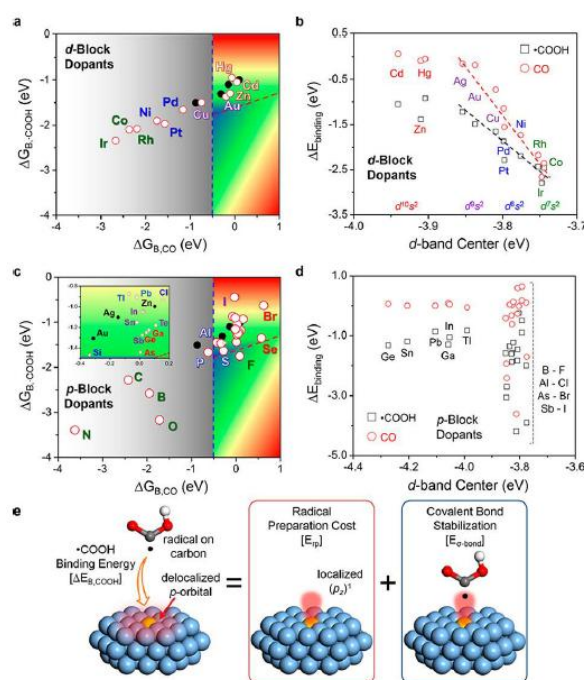

Hyungjun Kim, Hyung-Kyu Lim, and Hyeyoung Shin

Graduate School of EEWS, Korea Advanced Institute of Science and Technology

291 Daehak-ro, Yuseong-gu, Daejeon 305-701, KOREA

linus16@kaist.ac.kr

CO<sub>2</sub> conversion is an essential technology to develop a sustainable carbon economy for the present and the future. Many studies have focused extensively on the electrochemical conversion of CO<sub>2</sub> into various useful chemicals. However, there is not yet a solution sufficiently high enough efficiency and stability to demonstrate practical applicability. A key obstacle here is mostly due to the limited performance of the catalysts in terms of activity, stability, etc. To improve and tailor the catalytic properties, it is thus required to understand the operational mechanism of the various possible CO<sub>2</sub> reduction pathways and identify the mechanistic role of catalysts. In this talk, we use high-throughput quantum mechanics (QM) catalyst screening (coupled with continuum description of solvation effects) to discover new catalysts expected improve the performance of the electrochemical CO<sub>2</sub>-to-CO conversion by decreasing the overpotential by 0.4-0.5 V. We discovered the covalency-aided electrochemical reaction (CAER) mechanism in which *p*-block dopants have a major effect on the modulating reaction energetics by imposing partial covalency into the metal catalysts, thereby enhancing their catalytic activity well beyond modulations arising from *d*-block dopants [1]. We expect this work to provide useful insights to guide the development of a feasible strategy to overcome the limitations of current technology for electrochemical CO<sub>2</sub> conversion.

<sup>2</sup>University of Freiburg, Department of Microsystems Engineering – IMTEK,  
Laboratory for Process Technology, Georges-Köhler-Allee 103, 79110 Freiburg, Germany

Oxygen reduction reaction (ORR) is an important process on the cathode of polymer electrolyte fuel cells [1]. Crucial for the cost-effective exploitation of these devices in future is to use a precious-metal-free material as catalyst. Recent development of alkaline polymer electrolytes [2] has opened up possibilities to use nickel as alternative cathode catalyst. Particularly interesting application of Ni/Cr material is the alkaline polymer electrolyte fuel cells which have been increasingly recognized as a solution to overcome the dependence on noble metal catalysts. The key challenge is to increase the exchange current density of chromium decorated nickel electrodes by enhancement of the active surface area of the electrode itself. While ORR on Pt has been investigated using modelling in great detail [3] there are sparse studies [4; 5] on Ni in alkaline environment. Comparing to Pt and Ag, Hansen et al. [5] have found too high surface reactivity combined with electrode stability limited in small ranges of pH and electrode potentials.

In the present contribution, we study the mechanisms and the kinetics of the electrocatalytic ORR on pure Ni(111) surfaces and on Ni(111) surfaces decorated or doped by Cr. Using density functional theory and transition state theory we elucidate possible routes of the ORR and calculate the reaction rates in cell operation conditions, i.e. at presence of solvent, finite temperature and electrode potential. First we devise and optimize several atomistic model structures varying Cr surface doping and Cr surface coverage and applying multiple constraints from x-ray photoelectron spectroscopy (XPS) data. A sample model structure is depicted in Figure 1. For the resulting structures we investigate all possible surface elementary processes, such as adsorption and desorption, surface diffusion, hydrogen transfer, and O–O cleavage, for the cathode half reaction  $\frac{1}{2} \text{O}_2 + 2\text{e}^- + \text{H}_2\text{O} \rightarrow 2\text{OH}^-$ . In addition, we vary the surface coverage and consider the influence of spectator co-adsorbates (O, OH).

We show that modifications of the Ni surface with Cr as well as different surface coverages lead to strong variation of the elementary ORR rates and thus to various ORR routes, indicating qualitative different behavior of the catalyst. In the discussion we rationalize the findings with cyclic voltammetry (CV). Furthermore, we systematically derive a design strategy for improving the performance on the device level based on the full reaction kinetics simulation based on the calculated rates. The acquired data will be used in a holistic device-level approach, for example by coupling the kinetic model with mass/charge transport in fuel cell.

# Discover a Role of Ionic-Liquid in Electrochemical CO<sub>2</sub> Reduction by Using QM/MM Method

Hyung-Kyu Lim, Hyungjun Kim\*

*Graduate School of EEWS (Energy, Environment, Water and Sustainability)*

*Korea Advanced Institute of Science and Technology, 291 Daehak-ro, Yuseong-gu, Daejeon 305-701, Korea*

*zinnia7@kaist.ac.kr*

For the mitigation of global-warming problems and the sustainable development of the inevitable carbon-based economy, carbon dioxide (CO<sub>2</sub>) conversion technology has been regarded as one of the most important and urgent current scientific issues. Many researchers anticipate the efficient transformation of CO<sub>2</sub> from various emission sources into more valuable chemicals and fuels. Among the various ongoing attempts, which are categorized as biochemical, thermochemical, electrochemical, and photo-assisted electrochemical processes, the electrochemical method has certain merits in terms of high reactivity at ambient conditions and good extensibility from small to large-scale processes. Also, the possibility of direct integration with renewable electric sources adds more potential to the electrochemical method as a promising route for CO<sub>2</sub> conversion. A number of studies have been performed to improve performance of electrochemical CO<sub>2</sub> reduction on various catalyst and electrolyte systems, however it still has many scientific and engineering issues to be elucidated and improved, to achieve commercial-level technology. In 2011, the promising effect of ionic-liquid on the electrochemical CO<sub>2</sub> reduction performance have been reported that the mixture electrolyte contains ionic-liquid (18 mol% Emim-BF<sub>4</sub>) and water lowers the over-potential of CO<sub>2</sub> to CO reduction process on silver electrode as only 0.17 V from the equilibrium potential as well as suppress the competitive hydrogen evolution reaction effectively.[1] Further experimental studies have been tried to figure out the mechanism of lowering over-potential with ionic-liquid water mixture electrolyte,[2, 3] but the detailed understanding of complex electrochemical system has not been achieved. In our research, we developed the new grid-based QM/MM (Quantum Mechanics/Molecular Mechanics) methodology which can effectively handle the complex electrostatic interaction between catalyst and mixed electrolyte, and theoretically figured out the main role of ionic-liquid and water mixture electrochemical CO<sub>2</sub> reduction system.

The lithium sulfur (Li-S) battery is currently receiving much attention due to its supreme energy density, i.e., estimated to *ca.* 500 to 700 Wh/kg at the prototype cell level. Although it is a relatively “old” technology, world-wide interest came first when hierarchical carbon cathodes were used to improve the capacity retention.<sup>1,2</sup> In this scheme, sulfur is loaded in the micropores or mesopores of carbon particles, while the carbon particles themselves are immersed in the surrounding electrolyte, creating a liquid phase in between. To better understand the discharge mechanisms, especially the benefits of applying the hierarchical carbon cathode scheme, theoretical modeling is a powerful tool. Unfortunately, none of the current Li-S battery models take into account the hierarchical microstructure of the carbon cathode.

We here propose a physical discharge model for Li-S batteries, taking in consideration the cathode carbon microstructure through a multi-scale simulation approach.<sup>3</sup> In this model, solved within our MS LIBER-T computational framework,<sup>4</sup> the transport of species such as lithium cations ( $\text{Li}^+$ ), anions such as TFSI, native sulfur  $\text{S}_8$  and various polysulfides  $\text{S}_y^{2-}$  (5 different species) across the cell occurs in the liquid electrolyte. Additionally, species are also allowed to shuttle locally between the liquid phase and the electrolyte within micropores/mesopores. Electrochemical and chemical reactions may occur in both regions. Solid species precipitation, especially  $\text{Li}_2\text{S}$ , consume the active surface area of the carbon particles as well as of the pore surfaces. All these factors add to the complexity of the model, thus numerical efficiency is also a significant factor for practical use.

There are generally three theories for transport in electrolytes: the Poisson-Nernst-Planck equation, the dilute solution theory, and the concentrated solution theory. The Poisson equation is relatively unstable and may cause numerical convergence problems. The dilute solution theory requires the definition of an electrostatic potential in the solution, which may increase the computational load and most battery electrolytes are far from dilute. The concentrated solution theory is rather complicated apart for the binary electrolyte case, and in the Li-S batteries there are numerous charged species necessary to address. Hence, in order to compute the species transport in an efficient way, we here use a different approach, where the concentration profile of the anion in the liquid phase is self-adjusted to meet the charge neutrality condition, while the transport equations of all other species;  $\text{Li}^+$ ,  $\text{S}_8$ , and polysulfides, are solved. At the same time, fluxes of species between the various pores and the liquid phase electrolyte are obtained. Since long chain polysulfides are generated and consumed by reduction during discharge and dissolved into the electrolyte, the diffusion coefficients of all species are updated over time according to the altered electrolyte viscosity. In more detail, both  $\text{S}_8$  and long chain polysulfides affect the viscosity by their volume fraction applying Einstein's theory for viscosity. A finite volume method is implemented for the conservation of mass, resulting in simulation times typically less than one hour on a standard PC. The efficiency of our algorithm is discussed and exemplified by some realistic Li-S battery test cases.

[alejandro.franco@u-picardie.fr](mailto:alejandro.franco@u-picardie.fr)

A multiparadigm simulation tool is reported here in the frame of electrochemical energy conversion and storage devices. The tool is based on a new methodology able to couple on-the-fly two of our in house computational codes: the Kinetic Monte Carlo (KMC) code called MESSI<sup>1</sup> (*Monte Carlo Electrochemical Software for System Innovation*) with the simulation package MS LIBER-T (*Multiscale Simulator of Lithium Ion Batteries and Electrochemical Reactor Technologies*).<sup>2,3</sup> This coupling is achieved thanks to an algorithm we have recently developed and called Electrochemical-Variable Step Size Method (E-VSSM) allowing KMC simulations to communicate on-the-fly with continuum models.

An application example is illustrated here, concerning the investigation of Perfluorinated Sulfonic Acid Polymer Electrolyte Membrane (PEM) degradation in PEM Fuel Cells.<sup>4</sup> The electrochemical reactions in the electrodes are simulated by the KMC code, in a similar fashion we reported in Ref. 1. Reactions described include the Hydrogen Oxidation Reaction in the anode, the H<sub>2</sub>O<sub>2</sub> formation in the anode and in the cathode, and the Oxygen Reduction Reaction in the cathode. The crossover of H<sub>2</sub>/O<sub>2</sub> through the PEM, the species transport and elementary reactions responsible of the H<sub>2</sub>O<sub>2</sub> decomposition catalyzed by Fenton's cations and the side-chains detachment due to OH<sup>•</sup> and OOH<sup>•</sup> radicals attack, are described through coupled partial/ordinary equations solved with MS LIBER-T following a fully continuum-based scheme originally proposed by us<sup>5,6</sup> and later followed by other authors.<sup>7,8</sup> In our approach, these equations have as boundary conditions the chemical potentials and reaction rates calculated by the KMC code. Furthermore, the instantaneous feedback between the PEM degradation and the conductivity evolution (impacting the cell performance) is described. In such a way, the overall model is able to resolve the competitive processes at multiple temporal scales and predict performance decay over long simulated times (> 500 h). Results obtained for multiple operation conditions (imposed current density, temperature, Fenton's cations injection rates...) are discussed in comparison with experimental data.

# Electrochemical Studies at an Interface between Two Immiscible Electrolyte Solutions for CO<sub>2</sub> Reduction

Hye Youn Han, Farhana Sharmin Diba and Hye Jin Lee\*

*Department of Chemistry and Green-Nano Materials Research Center, Kyungpook National University,  
80 Daehakro, Buk-gu, Daegu, 702-701, Republic of Korea  
hyejinlee@knu.ac.kr*

In this poster, we demonstrate an electrochemical approach utilizing an interface between two immiscible electrolyte solutions (ITIES) for the reduction of CO<sub>2</sub>. An electrochemical H-cell was designed to contain water and 1,2-dichloroethane electrolyte solutions interfaced with Nafion 115 membrane. The aqueous electrolyte composed of potassium bicarbonate placed at an anode providing protons which can then pass through the Nafion 115 membrane reaching to 1,2 DCE phase where CO<sub>2</sub> reduction occurs at a gold working electrode (surface area of 1 cm<sup>2</sup>). Two different hydrophobic organic supporting electrolytes in 1,2-DCE were investigated including tetraoctylammonium perchlorate and tetrabutylammonium perchlorate and their performance in improving CO<sub>2</sub> reduction efficiency were compared. Linear sweep voltammetry (LSV) was performed to verify the CO<sub>2</sub> reduction reaction at the ITIES under N<sub>2</sub> only and in the presence of CO<sub>2</sub> in 1,2-DCE phase. Also the CO<sub>2</sub> purging time, concentration of organic supporting electrolytes alongside applied voltage for the efficient CO<sub>2</sub> reduction were studied. Immediately after the reduction of CO<sub>2</sub> via applying -1.5 V (vs Ag/AgCl) for 1 h using chronoamperometry under the condition of purging CO<sub>2</sub> at room temperature, the catholyte solution were analyzed using UV-vis spectrometry and high performance liquid chromatography. Our preliminary results show that formic acid can be produced via CO<sub>2</sub> reduction at the ITIES and further quantitative analysis is underway.

Fig.1 Representative LSVs for the reduction of CO<sub>2</sub> at an interface between water and 1,2-DCE electrolyte solutions. Scan rate = 20 mV/s. Solid line represents the LSV result obtained after applying -1.5 V (vs Ag/AgCl) for 1 h under CO<sub>2</sub> purging. Dotted line is the LSV data for only N<sub>2</sub> purging in 1,2-DCE electrolyte solution in the absence of CO<sub>2</sub>. Inset shows the UV-vis spectrum for the analysis of catholytes.

# Synthesis of High Ionic Conductive $\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$ Solid Electrolyte by a Sol-gel Process

Lithium batteries with high energy density are required for the rapidly growing markets of electric vehicles and mobile electronic devices. High-voltage battery system is one of the ways to achieve high energy lithium batteries [1]. However the practical use of high-voltage lithium batteries is hampered by the intrinsic problems of the conventional batteries: narrow electrochemical window and poor cycle stability of liquid electrolyte [2]. Furthermore safety issues are the greatest concern for conventional lithium-ion batteries. All-solid-state lithium batteries with solid electrolyte can play a key role to overcome these problems. All-solid-state batteries have problems, however, their low energy densities compared with liquid electrolyte lithium batteries resulting from the low ionic conductivity of the solid electrolyte and the electrolyte/electrode interfacial resistance [3]. The garnet-type solid electrolyte lithium lanthanum zirconium oxide,  $\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$  (LLZO), has been reported lithium as superionic conductors performing high ionic conductivity of  $2 \times 10^{-4} \text{ S cm}^{-1}$  at room temperature, high voltage window beyond 5 V with excellent stability [4-5]. In this study, garnet-type LLZO solid electrolyte was prepared by sol-gel based Pechini method [6] and their electrochemical properties were characterized. The cubic phase stability of LLZO and their ionic conductivity were investigated with voltage beyond 5 V. We would like to acknowledge the financial support from the R&D Convergence Program of NST (National Research Council of Science & Technology) of Republic of Korea.

Graduate Institute of Applied Science and Technology, National Taiwan University of Science and  
Technology 106 Taiwan  
HLCHOU@mail.ntust.edu.tw

## ABSTRACT

To make direct methanol fuel cell technology commercially viable, the principle drawbacks, namely high anode and cathode Pt-loadings and the sluggish kinetics of the anodic methanol oxidation reaction (MOR) need to be addressed. Several important investigations, related to the design and development of electrode configurations, have shown that the reaction kinetics of the MOR depend strongly on the surface's structure and size, together with the amount and degree of dispersion of the catalytic nanoparticles, as well as the nature of the support materials. To fully comprehend the functional effect of these controlling parameters on the electrochemical reactions an understanding of the relationship between the structural features and the corresponding reaction kinetics is necessary. Experimentally determined relationships can then be connected with theoretical considerations to achieve a deeper understanding, thus providing us with the knowledge to improve the catalysts performance. This lecture presents our recent work combining systematic experimental electrochemical measurements with a density functional theory (DFT) computational approach, directed towards the investigation of two key issues, namely: (1) the nano-size effect of Pt catalysts on the catalyst-size-dependent surface coverage of  $\text{OH}_{\text{ads}}$ ,  $\text{CO}_{\text{ads}}$  and its relationship to the energetics of the MOR, (2) the catalytic activities of ternary  $\text{Fe}_{1-x}\text{PtRu}_x$  nanocrystals in enhanced MOR. Our investigations into methanol oxidation show that, in contrast to bulk Pt, a relatively higher  $\text{CO}_{\text{ads}}$  coverage on the nano-sized Pt catalyst is observed from the *in situ* EC-FTIR investigations. Surface coverage models for the electrocatalytic MOR on bulk and nano-sized Pt catalysts are proposed using the combined knowledge gained from *in situ* EC-FTIR and DFT computational results. The chemical transformation reaction of binary FePt nanocrystals (NCs) in solution phase was used to synthesize a series of  $\text{Fe}_{1-x}\text{PtRu}_x$  NCs. The size, structures, compositions and alloying extents of the NCs were analyzed by transmission electron microscopy (TEM), X-ray diffraction (XRD) and X-ray absorption spectroscopy (XAS). Measurements of the catalytic activity of ternary  $\text{Fe}_{35}\text{Pt}_{40}\text{Ru}_{25}$ ,  $\text{Fe}_{31}\text{Pt}_{40}\text{Ru}_{29}$ ,  $\text{Fe}_{17}\text{Pt}_{40}\text{Ru}_{43}$ , binary  $\text{Fe}_{58}\text{Pt}_{42}$  and PtRu NCs showed that  $\text{Fe}_{31}\text{Pt}_{40}\text{Ru}_{29}$  NCs had the highest alloy extent and the lowest onset potential for the methanol oxidation reaction (MOR) among the ternary NCs. Furthermore, the ternary  $\text{Fe}_{1-x}\text{PtRu}_x$  NCs showed a superior ability to withstand CO poisoning compared to binary  $\text{Fe}_{58}\text{Pt}_{42}$  and PtRu NCs. The origin for the anti-CO poisoning was investigated by determining the adsorption energy of CO on the NCs surfaces and the charge transfer from Fe/Pt to Pt using a simulation based on density function theory. The results suggested that with the addition of a new metal into binary PtRu/PtFe NCs, the ability of ternary  $\text{Fe}_{1-x}\text{PtRu}_x$  NCs to withstand CO poisoning in the MOR can be greatly enhanced because the bonding of CO-Pt on the NC's surface was weakened. Overall, our results have opened a simple route for the discovery of new metal alloyed catalysts for fuel cell applications. The proposed models that we have derived show reasonably corroboration with the observed electrochemical measurements.

[bilewicz@chem.uw.edu.pl](mailto:bilewicz@chem.uw.edu.pl)

Lyotropic liquid crystalline systems are excellent carriers for drugs due to their biocompatibility, stability in aqueous environment and well defined structure that allows hosting significantly larger amounts of drugs, as compared to other carriers e.g. liposomes or gold nanoparticles. Holding the drug inside the mesophase gel or cubosome/hexosome nanoparticle may decrease its toxic effects towards healthy cells while appropriate mechanisms can stimulate the release of the drug from the carrier when it approaches the cancer cell environment [1-4]. Drug diffusion and kinetics of release from the mesophase depend among other factors on the nanostructure and aqueous channels sizes which are defined by the amphiphilic molecules used for the formation of the liquid crystalline phase. The channels diameters can be also increased by adding hydration increasing surfactants to the main lipid forming the mesophase [2]. Here we present the electrochemical studies of drug transport and sustained drug release in lyotropic cubic phases and cubosomes. Using chronocoulometry and voltammetry at micro and large electrodes we show the dependence of diffusion coefficients of an electroactive drug on the size of the channels. Moreover, we demonstrate that profiles of drug release may depend on pH, since the liquid crystalline phase may change with pH. or drug interactions with the lipidic bilayers forming the channel walls in the mesophase can be modified. Interactions between the drug and the cubic phase can be modified by using acidic additives that are incorporated into the cubic phase structure.

oswiech@chem.uw.edu.pl

Over the past decade, metallic nanoparticles, especially gold nanoparticles (AuNPs) have been investigated extensively as they possess unique electronic, optical, and catalytic properties.<sup>1</sup> AuNPs can be used as multifunctional platforms for biomedical applications such as contrast and imaging agents for diagnostic purposes and gene or drug delivery.<sup>2</sup> Several targeting ligands such as monoclonal antibodies, sugars, hormones, peptides, vitamins, or other small organic molecules can be used for specific biological recognition. An alternative (and novel) functionalization strategy is to use host-guest cyclodextrin (CD) inclusion complexes to assemble targeting functionality.<sup>3</sup>

We synthesized the new conjugate of  $\beta$ -cyclodextrin and lipoic acid with pH-sensitive triazole linker to immobilize the oligosaccharide on the gold electrode or gold nanoparticles surface, Figure 1. We investigated their usefulness as carriers for anthracycline drugs. The formation of CD-drug complex and the release of doxorubicin and daunorubicin at various pH were studied using chronoamperometry and compared with cyclic voltammetry technique. The immobilization of anticancer drugs on the gold nanoparticles by creation of pH sensitive inclusion complex improves the efficiency and selectivity of the drugs and helps to prevent multi-drug resistance. In addition, the using of appropriately modified cyclodextrin (CD) protects not only against cardiotoxic effects of the drugs, but also allows the release of the drug in the tumor environment. Electrochemical studies were confirmed by MTT cytotoxicity tests and visualized by confocal microscope.

The discovery of antibiotics was a milestone in the human fight against infectious diseases and has led to the substantial increase in quality of human's life. However, rapidly increasing number of multi-drug resistance pathogens resulted in a continuous need for new active compounds with strong activity. One of the most promising groups of compounds includes antimicrobial peptides (AMPs) [1,2]. These are small naturally occurring peptides with molecular mass less than 10 kDa and usually positively charged. Antimicrobial peptides are functional substances in the innate immune system of virtually all forms of life and they constitute a first line of defense against pathogens [3]. They display a broad range of activity on bacteria, fungi and parasites as well as on several cancer cell lines. Therefore, they have enormous potential as novel therapeutic agents.

Here we present the results of our studies on interactions of two natural antimicrobial peptides: cecropin B (from the hemolymph the giant silkworm *Hyalophora cecropia*) and anoplin (from the venom of the solitary wasp *Anoplius samariensis*) with model lipid membranes. The biomimetic lipid films were composed of: a) phosphatidylcholine and cholesterol, b) phosphatidylethanolamine and phosphatidylglycerol, reflecting the eukaryotic and bacterial cell membrane, respectively. Firstly, the influence of peptides on the behavior of lipid membranes was examined by means of surface pressure and Brewster Angle Microscopy. The experiments performed using Langmuir trough allowed us to determine the affinity of peptides to particular lipid components of the cell membranes. To better mimic the natural membrane, we prepared lipid bilayers by transferring the lipids on solid support using the combination of Langmuir-Blodgett and Langmuir-Schaefer techniques. The action of antimicrobial peptides was investigated by means of Cyclic Voltammetry, Electrochemical Impedance Spectroscopy and Atomic Force Microscopy. We have also employed the molecular modeling methods to determine structural details of peptide-lipid interactions.

# Electrocatalytic glucose oxidation in suspension and film consisting charged Au and Pt nanoparticles

Marcin Opallo, Joanna Dolinska, Palanisamy Kannan, Volodymyr Sashuk, Janusz W Sobczak, Zbigniew Kaszukur, Wojciech Lisowski, Martin Jonsson Niedziolka

*Institute of Physical Chemistry, Polish Academy of Sciences, Warszawa, Poland  
mopallo@ichf.edu.pl*

It is generally understood that the neighboring surface atoms of different elements of alloys participate in the electrocatalytic reaction of the same molecule, contributing to the synergistic effect [1]. It has been also demonstrated, that electrocatalytic synergy results from close proximity of the different bulk metals surfaces [2]. One may expect that the film consisting of nanoparticles of different metals may exhibit synergistic effect in certain electrocatalytic reactions. Here, we tested this hypothesis with glucose electrooxidation on Au and Pt nanoparticles. This is because this reaction was earlier studied on films consisting Au-Pt alloy nanoparticles and synergistic effect was reported [3-5]. We extended our study to suspension of Au and Pt nanoparticles as electrocatalysis is observed on inert electrodes immersed in suspension of electrocatalytic nanoparticles [6,7]. These studies were so far restricted to suspensions of single type of nanoparticles in quiescent conditions.

The nanoparticulate film electrodes were prepared by layer-by-layer technique or by droplet deposition from suspensions of oppositely charged Au and Pt nanoparticles on ITO substrate. They were covered by 1-(11-mercaptoundecyl)-ammonium (positively charged) or 11-mercaptoundecanoate (negatively charged) functionalities. The bimetallic film is formed (as seen by Scanning Electron Microscopy) due to electrostatic interactions. The presence of both Au and Pt nanoparticles in film was identified by X-ray Powder diffraction and X-ray photoelectron spectroscopy. The shape of voltammetric curves in glucose alkaline solution is different than observed on electrodes modified only with Au or Pt nanoparticles. Most importantly, the significant shift of onset potential as compared to electrodes prepared only from platinum (ca. 0.45 V) or gold (ca. 0.6 V) nanoparticles, indicating synergistic effect. Significant increase of the voltammetric current is also seen,

For experiments in suspension Au and Pt nanoparticles of the same charge (citrate functionalized) were employed. Having like charges prevents nanoparticles from aggregating and precipitating. The experiments were performed at rotating glassy carbon electrode with methodology described earlier [8]. The voltammetric current density in bimetallic suspension is approximately fourfold larger than measured for Pt nanoparticles in suspension and three orders of magnitude larger than observed for a suspension of Au nanoparticles. The features of voltammograms are classically different from voltammograms obtained for suspensions of Au or Pt nanoparticles under the same conditions. They also indicate synergistic effect. The most significant voltammetric signal arises mainly from the electrocatalytic oxidation of glucose at nanoparticles adsorbed on the glassy carbon electrode as confirmed by the increase of the voltammetric current during experiment and X-ray photoelectron spectroscopy performed after voltammetric experiment.

# Magnetic Nanoparticles and Magnetoliposomes as Anticancer Drug Carriers

Paweł Krysiński, Dorota Nieciecka, Aleksandra Joniec

<sup>1</sup> Faculty of Chemistry, University of Warsaw, 02-093 Warsaw, Poland)

Superparamagnetic iron oxide nanoparticles (SPIONs) have attracted wide attention due to magnetic properties and the ability to chemically modify their surfaces. Therefore it appears that SPIONs could be ideal candidates as carrier platform in targeted drug delivery, where the drug/carrier conjugate can be guided to the specific site with an aid of external magnetic field. Magnetic nanoparticles have been focusing an increasing interest especially due to the possibility of limiting the adverse side-effects of traditional therapy, elongated time of drug release, increased efficiency, as well as an improvement in drug activity towards malignant cells and tissues.

We synthesized nanoferrites and modified their surface by adsorptive or covalent binding of doxorubicin (DOX) – a potent anti-cancer drug. We also incorporated hydrophobic SPIONs into the lipid bilayer of liposomes loaded with the same drug. For both cases the drug load, efficiency and release under the effect of pH, temperature and alternating magnetic field were monitored by means of spectroscopic and electrochemical techniques.<sup>1,2,3,4</sup> The development of such conjugate systems as reported here, can result in much more efficient targeting of disease tissues and a substantial reduction of the required therapeutic dosage of a drug, thereby minimizing its adverse side effects. In addition, the superparamagnetic core can itself be used therapeutically for the creation of localized magnetic hyperthermia, enhancing also the drug release. In our research we have focused also on the interaction of nanoparticle/drug conjugates with biomimetic membrane systems and cancer cell lines. The mechanism of SPION crossing through the lipid bilayer in cells is still unknown. Therefore it is very important to study the transport of nanoparticles and their permeation into the target cells.

Left: Magnetoliposomes with DOX accumulated with a magnet at the wall of a vial (B – liposomes without SPIONs). Right: CV of DOX released from magnetoliposomes under temperature stress.

Considerable progress has been achieved in constructing artificial signal chains which follow natural examples. One approach is based on the construction of protein arrangements using the redox protein cytochrome *c* (cyt *c*) and exploiting its self-exchange capabilities [1].

Originally the layer-by-layer adsorption technique has been used for a defined biomolecule arrangement. Different building blocks are applied including polyaniline derivatives, DNA and nanoparticles. Furthermore, the construction of bi-protein assemblies with catalytic properties have been demonstrated, e.g. with sulfite oxidase [2]. These architectures allow the adjustment of the electrode response to the respective substrate by the numbers of deposited layers without using any soluble shuttle molecule.

Based on these results a more complex tri-protein architecture has been created on a modified gold electrode [3]. Here two signal chains can be established within an unseparated matrix and switched on and off by the electrode. For this purpose cellobiose dehydrogenase and laccase have been co-immobilised within the layered cyt *c* structure. Enzyme molecules in different distances to the electrode can be addressed. The redox state of cyt *c* can be used for tuning the activity of the biocatalysts. Whereas the CDH allows lactose detection, the activity of laccase is determined by the oxygen content of the solution.

Recent investigations demonstrate that such defined electron transfer chains can not only be obtained in protein assemblies, but also within a protein crystal with more defined positions of every redox center within the structure [5]. Such investigations are based on findings of an improved protein crystallization by means of a small molecule – a calixarene [4]. Consequently the procedure has been adopted to electrochemical studies and cyt *c* was co-crystallized with *p*-sulfonato-calix[4]arene on a modified gold electrode. Although only a part of the electrode surface was covered by the crystals a well-defined and rather large electrochemical response has been found. This has been investigated kinetically and compared with the behavior of cyt *c* multilayer structures prepared by the LbL technique. Obviously efficient electron pathways exist within the crystals which can be rationalized by the structural data.

Such an approach represents an interesting aspect in the developments of systems confining biological electron transfer cascades to technical devices by fixing protein-protein reactions to electrodes in the immobilized state and may open up the door to new functional systems.

Bioelectrochemistry has been extremely valuable in elucidating the catalytic mechanism of respiratory redox enzymes, although in almost all cases only globular enzymes or water-soluble subcomplexes have been investigated. In biology, however, many respiratory reactions are catalysed by redox enzymes that reside in the lipid membrane, where they play a major role in almost all metabolic processes, including photosynthesis and biochemical processes such as the nitrogen cycle. The relative lack of bioelectrochemical studies of membrane proteins are due to their amphiphilic nature, which make them difficult to handle experimentally, especially in sensitive electrochemical experiments where proteins are prone to denaturation on the electrode surface.

By modifying ultra-flat electrode surfaces with so-called tethered bilayer lipid membranes (tBLMs), supramolecular platforms can be constructed that enable the electrochemical characterisation of membrane-bound redox enzymes contained within the tBLM. In this presentation, two examples will be discussed in which tBLM systems have elucidated respiratory processes. In the first example, the inner membrane architecture of *Shewanella oneidensis* was mimicked by incorporating the menaquinone-7 (MQ-7) dehydrogenase, CymA, within the tBLM. Quartz-crystal microbalance with dissipation (QCM-D) is used to detect the binding of CymA to globular partner proteins from the periplasm and with cyclic voltammetry the electron transfer from MQ-7 to CymA and then to the partner proteins is monitored. In the second example, a membrane-bound [NiFe]-hydrogenases (MBH), which has been extensively studied for applications in hydrogen–oxygen fuel cells, was incorporated in the tBLM. The MBH of *Ralstonia eutropha* was used in this study as compared to other MBHs it is relatively insensitive to deactivation by oxygen. Previous bioelectrochemical studies with the water soluble subcomplex of MBH, lacking the membrane-bound subunit, showed that this MBH is inactivated at high potentials, especially in the presence of oxygen. In contrast, cyclic voltammetry and chronoamperometry experiments show that MBH, when in equilibrium with the quinone pool in the tBLM, does not inactivate under oxidative redox conditions. Furthermore, although the MBH in the tBLM is still inactivated by O<sub>2</sub>, reactivation was found to be fast even under oxidative redox conditions. We propose that this enhanced resistance to inactivation is due to the fact that MBH is in a more native-like environment in the tBLM.

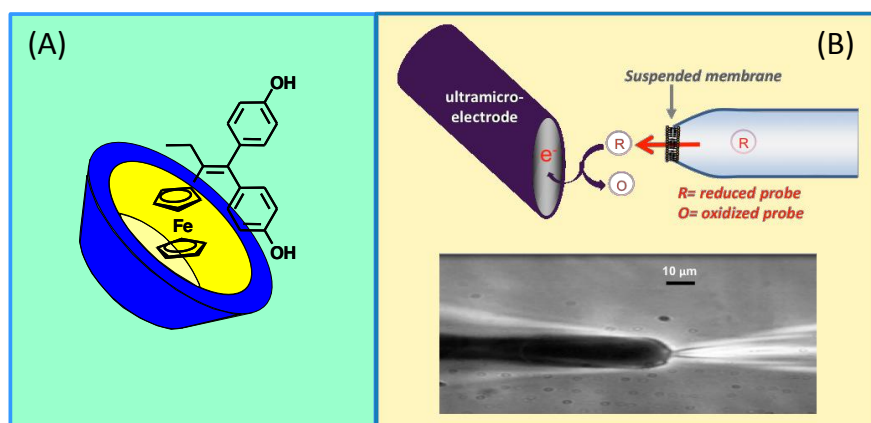

# Contribution of Electrochemistry to Investigate the Solubilization and Transport Through Suspended Membranes of Redox Active Molecules

O. Buriez

Drug delivery is a central issue for the success of many pharmaceutical strategies. In this context, electrochemistry has been used as a tool to monitor solubilization and transport of biomolecules [1]. For instance, it was demonstrated that cyclodextrins can be used to solubilize ferrocene-based anti-cancer drug candidates in water without changing their biological activity (Figure A) [2]. On the other hand, we have used two complementary approaches to electrochemically probe both the interactions and the crossing of these valuable redox molecules in the presence of supported and suspended pure lipid membranes, respectively [3-5]. Supported membranes were obtained via the polarization of a glassy carbon electrode whereas solvent-free pure lipid suspended membranes were originally obtained by excision of giant vesicles (20 - 50  $\mu\text{m}$  in diameter). In the latter case, novel integration of patch-clamp and amperometry provided a powerful mean for quantifying, in real time, fluxes of molecules across real cell and artificial membranes (Figure B) [5].

(A) Solubilization of a ferrocene-based anti-cancer drug candidate. (B) Electrochemical detection of molecular species crossing suspended membranes.

Over the past two decades, functional supramolecular materials prepared with noncovalent interactions have attracted enormous attention because of their unique applications in electronics, photonics, light-energy conversion, biosensing, and catalysis. Recently, supramolecular materials with water-stability and adaptive encapsulation properties have become particularly attractive especially in biosensor development since most biological processes take place in aqueous environments and biological molecules such as proteins and enzymes are generally active in water. Moreover, the ability to encapsulate functional molecules in supramolecular networks enables the materials to hold great promise in tailoring and improving their functions for target-oriented applications. So far, several kinds of water-stable and adaptive materials have been developed, mainly based on metalcoordination interactions. As a result, it is imperative to explore other kinds of noncovalent interactions for the development of water-stable and adaptive materials with excellent properties.

Ionic interaction between oppositely charged species represents one of the strongest noncovalent interactions and has been widely used in self-assembly, typically as electrostatic self-assembly in solid state and ionic self-assembly in solution. All this work suggests that Coulombic interaction could be used as the noncovalent interaction to form supramolecular materials by self-assembly. While wide availability of charged species and the simplicity of their synthesis allow the ionic interactions to be used in synthesis of various functional materials, it remains a great challenge to utilize this kind of interaction to develop functional supramolecular materials with water stability and adaptive encapsulation property. This is because, on one hand, most of the charged species could easily dissolve in water because of the high dielectric constant of water ( $\epsilon = 78.5$ , at 25 °C) and thus the electrostatic interactions become significantly weakened in water. On the other hand, the large lattice energy in ionic compounds essentially limits their encapsulation property. Very recently, this interaction was utilized to create supramolecular ionic networks and supramolecular polymers by using multiple electrostatic bonds. This implies that ionic interaction could potentially provide the possibility to form water-stable and adaptive supramolecular materials by rationally designing the structure of the building blocks. However, such potential has not been explored so far.

Herein, we demonstrate a series of water-stable, adaptive, and electroactive supramolecular ionic materials (SIM) that is formed from the aqueous solutions of imidazolium-based dication and dianionic through ionic self-assembly. The formed SIM not only shows good thermostability and unique optical and electrochemical properties that are raised from precursors of the SIM, but also exhibits good water-stability, salt-stability, and adaptive encapsulation properties toward some heterocyclic cationic dye molecules. Firstly, we systematically studied the self-assembly behavior based on different carbon chains in imidazolium dications and its structure. Secondly, we found these SIM bears good adaptive inclusion property towards organic dyes and inorganic salt. Based on this, some kinds of biosensors including fluorescence and electrochemistry have been developed. Finally, the electronic property of this kind of SIM was investigated. And we found its electric conductivity was strongly dependent on the humidity. Based on this property, the solid electronic device with high sensitivity and stability was developed. The present study not only opens a new avenue to the preparation of the supramolecular materials, but also provides a versatile platform for (bio)sensing and electronic devices.

# First-Passage Statistics in Nanoelectrochemistry: Applications to Nano-Impacts

Enno Kätelhön, Shaltiel Eloul, Christopher Batchelor-McAuley, Kristina Tschulik,  
and Richard G. Compton

South Parks Road, Oxford, OX1 3QZ (United Kingdom)  
enno.kaetelhoe@chem.ox.ac.uk*

Stochastic processes play a crucial role in electroanalytical measurements near the theoretical limit of detection as well as in a variety of nanoelectrochemical set-ups, where the dimensions of the electrode are of the order of the average spacing of electroactive species. While classic electrochemical systems can be well described through locally-averaged analyte concentrations and Fick's laws, processes in the aforementioned systems are often determined by the stochastics of each individual analyte's Brownian motion [1]. Measured results may hence depend on a number of different first passage problems: When does a species hit an electrode for the first time? What is the probability that this species reacted at a particular other electroactive site beforehand? Or what is the average residence time in a zone of electron transfer?

Aside from applications in the investigation of biological membranes, single-molecule detection, molecular recognition, and many others, first-passage statistics are of particular interest in the fastly-developing field of nano-impacts. In nano-impact measurements, an electrode is exposed to a solution of freely diffusing nanoparticles, which, by virtue of their Brownian motion, will stochastically impact on the electrode. During collisions, they may either react due to their intrinsic electrochemical properties or catalytically enable a reaction between the electrode and electroactive species in solution [2,3]. Impacts can be observed as spikes in the measured electrode current, which provides insight into the detected particles' electrochemical properties and their sizing. As individual particles can be detected, a number of first-passage effects directly affect the measured currents in terms of the frequency of spikes, their magnitude, and shape.

In this talk, we discuss general aspects of first-passage statistics in the context of nanoelectrochemistry and demonstrate an analysis of a nanoparticle's average time of residence within the zone of electron transfer at a planar electrode. Additionally considering the effect of near-wall hindered diffusion, we find that nanoparticles generally experience hydrodynamic adsorption at surfaces, which can be quantified in great detail via a first-passage approach [4]. As our findings are generally applicable to systems that comprise of freely diffusing nanoparticles, the effect of hydrodynamic adsorption has wide implications on nanoparticle research.

# One-step Supramolecule Assembly of N-(aminobutyl)-N-(ethylisoluminol) Functionalized Gold Nanodots on Multiwalled Carbon Nanotubes and Their Applications to Sensors

H. Cui, H. L. Zhang, Z. L. Han

*Department of Chemistry, University of Science and Technology of China,  
Hefei, Anhui 230026, P.R. China  
hcui@ustc.edu.cn*

Based on the remarkable electronic, optical, thermal, high surface area properties, carbon nanotubes (CNTs) have been extensively investigated for chemical and biological application. Gold nanomaterials (AuNMs) are considered as the most common building blocks for current nanoscience due to the unique properties, including stability, biocompatibility and ease of self-assembly property. Take advantages of both CNTs and AuNMs, the combination of them could give rise to novel AuNMs–CNTs hybrid nanomaterials. Recently, in our group,<sup>1</sup> N-(aminobutyl)-N-(ethylisoluminol) (ABEI) functionalized gold nanodots (ABEI-GNDs) were successfully assembled onto the sidewalls of chitosan-modified multiwalled CNTs (cs-MWCNTs) via the reduction of HAuCl<sub>4</sub> with ABEI in the presence of cs-MWCNTs by virtue of covalent and noncovalent interactions. The proposed one-step strategy is green, simple and highly effective. The obtained hybrid nanomaterial exhibited excellent chemiluminescence (CL) and electrochemiluminescence (ECL) properties. Based on the excellent ECL performance of the novel hybrid nanomaterials, an ECL immunosensor was developed for the determination of N-terminal pro-brain natriuretic peptide (NT-proBNP).<sup>2</sup> The hybrid nanomaterials were coated onto the surface of ITO electrode via their film-forming property. Then, anti-NT-proBNP antibody was attached to the surface of modified electrode by virtue of amide reaction via glutaraldehyde. Finally, when NT-proBNP was captured by its antibody via immunoreaction, the ECL intensity decreased, which were used for the determination of NT-proBNP. The proposed ECL immunosensor demonstrated a quite wide linear range of 0.01–100 pg/mL and achieved low detection limit of 3.86 fg/mL, which was about 3 orders of magnitude lower than that obtained with electrochemistry method reported previously.<sup>3–4</sup> The present immunosensor is highly sensitive, simple, fast, selective, stable and reliable. It has been successfully applied to the determination of NT-proBNP in practical plasma samples. Furthermore, the proposed strategy might be used for the detection of other important clinically biomarkers. This work revealed that the as-prepared hybrid nanomaterial could be used as ideal nanointerface to fabricate sensitive biosensors.

# Supramolecular Biological Assemblies for Biosensors and Biofuel Cells

Cosnier Serge

*Département de Chimie Moléculaire UMR CNRS 5250  
Grenoble Alpes University, BP-53, 38041 Grenoble Cedex 9, France  
Serge.Cosnier@ujf-grenoble.fr*

With the aim to improve the performance of biomaterials, 3D structures were designed to create an oriented biomolecule monolayer or a high density of biological entity at the transducer surface. Owing to their high conductivity, inertness and electroactive surface area, graphene and carbon nanotube are widely used for the design of biosensors and biofuel cells [1,2].

In this context, we report the functionalization of a single graphene layer on a thin gold film by copper coordinated nitrilotriacetic acid attached to graphene via  $\pi$ - $\pi$  interactions with pyrene derivatives and the subsequent immobilization of biotinylated cholera toxin antigen. With the amplification of the SPR signal by graphene, a detection limit of 4 pg mL<sup>-1</sup> was obtained for the antibody anticholera toxin [3]. Carbon nanotube coatings were also functionalized with 4-aminonaphtoic acid. These carboxylated nanotubes exhibited an efficient direct wiring of hydrogenase allowing H<sub>2</sub> oxidation and hence the elaboration of a hydrogen/oxygen biofuel cell [4].

Increased attention has been also given to the functionalization of electrode and SPR surfaces by the combination of carbon nanotube coating with graphene, polypyrrole, polyacrylonitrile or polynorbornene films. For instance, deposition on carbon nanotube electrodes of reduced graphene oxide nanosheets functionalized by anthraquinone groups allows excellent electron transfer properties. Laccases were immobilized on the nanostructured electrode by the interaction between the anthraquinone moiety and the laccase hydrophobic pocket leading to efficient bioelectrocatalytic oxygen reduction [5]. The combination of carbon nanotube coating and an electropolymerized polypyrrole film of a protein: concanavalin A is also an original strategy for the non-covalent immobilization of glycoproteins via specific interactions with polymerized concanavalin A [6,7]. Finally, another approach concerns the fabrication of fiber tissue electrode from nanosized fibers containing carbon nanotubes. The latter were produced by electrospinning from a solution containing nanotubes and polyacrylonitrile. The biofunctionalization of the nanofiber electrodes was exemplified by chemical grafting of an enzyme model, polyphenol oxidase, onto the nanofiber tissue [8].

Daunorubicin (DNR) is an anthracycline antitumour drug, which finds application in the treatment of various types of cancer including leukemia, breast cancer, ovarian cancer, lung carcinoma, as well as several sarcomas [1]. However, the usage of this drug in the treatment is limited because of serious side effects including drug-induced heart failure. Therefore, numerous studies focus on the application of different drug delivery systems (DDS) such as for example carbon nanotubes to transport daunorubicin to cancer cells [2]. The influence of both free drug and drug adducts with single-walled carbon nanotubes (SWCNTs) as potential drug carriers on model biological membranes was investigated first using Langmuir technique. The model membranes were composed of 1,2-dipalmitoyl-*sn*-glycero-3-phosphothioethanol (DPPTE). Our previous studies revealed that application of the thiolipid allows one to transfer the layers onto solid support by means of both Langmuir-Blodgett method and self assembly and electrochemical methods such as chronocoulometry along with STM studies proved that the organization and structure of the transferred layers strongly depend on the mode of transfer [3].

Results of Langmuir studies show that daunorubicin easily incorporates into the DPPTE layers during their formation increasing significantly the area per molecule and causing immense fluidization of the layers. The observed changes depend on the concentration of the drug in the subphase [4]. Additionally, the dominating type of the driving forces responsible for the interactions (electrostatic or hydrophobic) depends on the organization of the layers. Cyclic voltammetry experiments revealed that DNR incorporation is easier into supported layers transferred by LB method than into SAMs because LB layers are less compact and hydrophobic interactions between the acyl chains of the thiolipid and hydrophobic anthraquinone part of DNR are facilitated. In the next step, the results of the interactions of the free drug with model membranes were compared with the results obtained for DNR attached to the SWCNTs by forming hydrazone with the nanotubes, which provides covalent bonding either at the ends or sides of the nanotubes [5]. Langmuir studies of mixed monolayers showed that even at the highest investigated content of the nanotubes in the monolayer, the changes in the properties of DPPTE monolayers were not as significant as in case of the incorporation of free drug, while electrochemical studies revealed that in the same time the surface concentration of DNR in supported monolayers is comparable to the reported surface concentration of the free DNR incorporated into supported DPPTE monolayers. Therefore, it may be concluded that the application of carbon nanotubes as potential DNR carrier allows for the incorporation of comparable amount of the drug into model membranes with simultaneous decrease in the negative changes in the membrane structure and organization, which is an important aspect in terms of side effects of the drug.

# On the Synthesis of Zinc-Tetrapyrridylporphine Complex for the Electrochemical Recognition of Bilirubin in Serum

Mei-Jywan Syu\*, Yao-Wei Hsu

Department of Chemical Engineering, National Cheng Kung University

No. 1, University Rd., Tainan, Taiwan 701

syumj@mail.ncku.edu.tw syumei2014@gmail.com

The aim of this work is to synthesize a metal-tetrapyrridylporphine complex with the inclusion ability for bilirubin. The metal-tetrapyrridylporphine complex thus prepared is a kind of stimulated-responsive gel. It owns regularity from its repeated and symmetric structure while, on the other hand, it also owns softness for the inclusion of the guest molecules into its flexible framework once the stimulation is applied. Via tuning the structure of the metal-organic complex with the stimulation, different applications could be expected. In this work, 5,10,15,20-tetra(4-pyridyl)-21H,23H-porphine (TPyP), a compound of porphyrin series is used as the precursor for the synthesis of the metal-organic complex. A basic unit scheme of the metal complex from TPyP precursor is shown in Fig. 1. The feasibility on the formation of the metal-organic gel with zinc(II) and ferrous(II), via the coordination of TPyP with a metal ion with the valence number of two, were studied. The formation of the metallic organic gel could be the consequence of not only via the hydrogen bonds, but also via the  $\pi$  interaction of the porphyrin plane donated from the electron pairs of the pyridyl groups laid on the four tops. The geometric symmetry of the TPyP is an essential feature contributed to the formation of the metallic organic crystal. The Zn(II)TPyP is further analyzed by a UV/Vis spectrophotometer and an FTIR (Figures 2(a), 2(b)) to confirm the characteristic peak and major bonds from the stretching and bending vibrations. The Zn(II)TPyP crystal is then fabricated onto the Au substrate for the electrochemical uptake of bilirubin. The results confirm the successful calibration of bilirubin concentration in the available clinical range with a sensitivity of  $0.336 \pm 0.021$  ( $\mu\text{A}/\text{cm}^2$ )/(mg/dL) by using this inclusion material.

Keywords: TPyP, porphyrin, pyridyl group, bilirubin, coordination

# DNA Bases Co-Adsorption at Gold Electrodes. An in-situ FT-IR Spectro-Electrochemical Study

Manuela Rueda, Julia Alvarez-Malmagro, Francisco Prieto  
*Department of Physical Chemistry University of Seville.*  
*c/ Profesor Garcia Gonzalez 1. 41012 Seville. SPAIN*  
*tfn. +34955421003*  
*marueda@us.es*

The interactions between complementary DNA bases play a significant role in genetic expression and replication. The co-adsorptions of these bases on solid substrates are important to understand the interactions of complementary bases interactions and the non-complementary bases interactions, that can induce genetic modifications, in organised interfaces similar to the biological interfaces. Moreover, the co-adsorptions of DNA bases are interesting in relation to technological processes as the manufacturing of biosensors with capabilities to detect epigenetic modifications or the design of nano-platforms for drug delivery.

In this respect, we have already started a systematic study of the co-adsorption of DNA bases on gold electrodes by combining modern in-situ FTIR techniques that provide chemical specificity and high sensitivity with electrochemical methods. Thus, the co-adsorption of thymine and adenine on gold thin-film electrodes from acid solutions has been previously studied by surface-enhanced infrared absorption spectroscopy in the attenuated total reflection mode (ATR-SEIRAS) [1]. The results suggest a rearrangement of both molecules on the electrode surface in a cooperative process in order to facilitate the Watson–Crick (W–C) and/or Hoogsteen (HG) interactions between the bases, as the atoms involved in these interactions are also the most probably sites of interactions with the metal. On the other hand, recent studies about the influence of pH on adenine adsorption on gold electrodes have shown that the two acid-base equilibriums of adenine are modified at the electrode interfaces [2, 3]. Moreover, our results about thymine adsorption on gold show that different tautomers can be stabilised on the electrode surface depending on the pH of the solution and of the electric potential.

In this communication the co-adsorption of the complementary DNA bases adenine-thymine and of guanine-cytosine on gold thin-film electrodes are studied in a wide pH range (from pH 1 to 12) by combination of ATR-SEIRAS and electrochemical experiments. They have been performed in perchlorate and either perchloric acid or hydroxide solutions, using H<sub>2</sub>O and D<sub>2</sub>O as solvents. Thin-film gold electrodes prepared by sputtering were used as working electrodes and electrochemical and some complementary SNIFTIRS experiments have been performed using Au(111) electrodes.

The spectrums of co-adsorbed bases are analysed as a function of potential at each pH value and are compared to the spectrums of each adsorbed base in the same experimental conditions. Different concentrations of each base are assayed in the sub-monolayer range. In this way the interactions between the different acid-bases and/or tautomeric forms of each DNA complementary base are determined. In the case of adenine-thymine co-adsorption the cooperative rearrangement of both molecules is confirmed and discussed based on  $\pi$ -stacking and dipole-dipole interactions among the different tautomeric and acid-base forms. In the case of guanine-cytosine the co-adsorption study is limited to basic media in order to achieve the simultaneous chemical adsorption of the two molecules in the same potential range and to avoid guanine oxidation. Guanine adsorption is stronger and induces the rearrangement of cytosine on the surface, even at lower concentrations.

Cancer antigen 19.9 (CA19.9) is the reference biomarker for pancreatic cancer, one of the most aggressive malignant tumors and leading cause of cancer-related deaths worldwide.<sup>1</sup> The determination of CA19.9 in pancreatic cyst fluid might improve diagnostic performance. In the framework of point-of-care testing, however, measuring CA19.9 during the endoscopy is a very challenging task, particularly when the biomarker concentration is very low. We focused on implementing electrochemical nanotechnologies suitable to detect CA19.9 with very high sensitivity and very low detection limits. Electrodes were modified with functionalized gold nanoparticles that were then modified with an antibody specifically tailored to bind CA19.9. Magnetic particles capped with a redox label (horseradish peroxidase, HRP) and a second antibody completed the immunosensor. Biorecognition was granted by the strong affinity between the antigen and the two antibodies. The sandwich-like immunosensor was integrated into a microfluidic device. Activation of the HRP labels with H<sub>2</sub>O<sub>2</sub> causes an amperometric-current transient proportional to the protein concentration. This immunosensor strategy successfully detects CA19.9 concentrations that are typically one order of magnitude lower than those obtained using the ELISA assay, and with a much higher sensitivity.

# A Rapid Detection of Biomarkers Applied by Electrochemical Biosensor Accelerated with an AC Electrokinetic Manipulation

Yu Cheng, Tzu-Ying Wu, and Hsien-Chang Chang\*

Department of BioMedical Engineering, Cheng Kung University, Tainan, Taiwan  
hcchang@mail.ncku.edu.tw

## Abstract

Fluorescent labelling and chromogenic reactions that are commonly used in conventional immunoassays typically utilize diffusion dominated transport of analytes, which is limited by slow reaction rates and long detection times. By integrating alternating current (AC) electrokinetics and electrochemical impedance spectroscopy (EIS), we construct an immunochip for rapid, sensitive, and label-free detection. AC electroosmosis (ACEO) and positive dielectrophoresis (DEP), induced by a biased AC electric field, can rapidly convect and trap the analyte onto an EIS working electrode within a few minutes (Fig. 1). We apply this system for the detection of the tumor marker, Alpha-feto protein (AFP,  $\alpha$ -fetoprotein). After AFP containing sample injected and reacted with antibody of AFP (Anti-AFP) will allow the change of electron-transfer resistance ( $R_{et}$ ) caused by the antibody-antigen (Anti-AFP-AFP) binding to be measured and quantified in real time (Fig. 2). The detection limit is able to reach 150 ng/ml of AFP (Fig. 3).

Fig.1. Comparison between the detection effect of the ACEO and non-ACEO

Fig.2. The Nyquist Plot of AFP

Fig.3. The calibration curve of AFP

Keywords: AC electroosmosis (ACEO), electro- chemical impedance spectroscopy (EIS),  $\alpha$ -fetoprotein

# Application of GroEL Complexes as Nano-sized Cargo

## Introduction

Chaperonin GroEL and co-chaperonin GroES are related to intracellular protein folding in *Escherichia coli*. GroEL is constructed by two heptameric rings of 57 kD subunits, and these rings are stacked back to back. GroES is a single heptameric ring of 10 kD subunits. GroEL binds a wide variety of substrate proteins in non-native states. After GroEL catches the substrate, GroEL binds ATP and GroES to form GroEL/GroES complex which has about 5 nm cavity for the encapsulation of substrates.

GroEL<sup>D52/398A</sup> is extremely defective in ATP hydrolysis [1][2]. In the presence of GroES and ATP, GroEL<sup>D52/398A</sup> produces a symmetric 1:2 GroEL-GroES complex (the “football”-shaped complex) in which both GroEL rings encapsulated substrate protein. Notably, the symmetric complex of GroEL<sup>D52A/D398A</sup> was extremely stable, with a half-time of ~150 h (~6 days). Furthermore, the two rings of GroEL<sup>D52/398A</sup> can be controlled individually to close the cavities by using nucleotide differences. In ADP, GroEL<sup>D52/398A</sup> can bind GroES to form a stable 1:1 GroEL-GroES complex in which one of GroEL rings contains an encapsulated substrate protein. This 1:1 GroELGroES complex (the “bullet”-shaped complex) is converted into the symmetric 1:2 GroEL-GroES complex when GroES is supplied in ATP.

The property of the GroEL<sup>D52/398A</sup> looks beneficial not only for folding the polypeptide but dispersing aggregatable nanoparticles and hydrophobic compounds. So, we tried to encapsulate a few varieties of the nanoparticles in the GroEL<sup>D52/398A</sup>.

## Experiments

Pt (Average  $\phi$  2 nm), FePt ( $\phi$  4 nm), CdSe/ZnS ( $\phi$  7nm), Au ( $\phi$  10 nm) and Ag ( $\phi$  5 nm) were used to encapsulate in GroEL as metal nanoparticles. In the case of nanoparticle encapsulation in one side of GroEL<sup>D52/398A</sup> cavities, 0.1-1.0  $\mu$ M GroEL<sup>D52/398A</sup>, 0.2-2.0  $\mu$ M GroES (2-fold mol of GroEL), and 1mM ATP were added to the sonicated nanoparticle solution. For two different nanoparticle encapsulation in both sides of GroEL<sup>D52/398A</sup> cavities, GroEL<sup>D52/398A</sup> which is bound to first nanoparticle was added to the same molar of GroES and 5mM ADP. The bullet-shaped GroEL<sup>D52/398A</sup> encapsulating first nanoparticle was mixed with the second nanoparticle solution for 1 minute, then, GroES and 1mM ATP were added to form the football-shaped complex. The specimen was stained with 0.5-1 % phosphotungstic acid (pH 4.0) and observed with an electron microscope (JEM-2000EX or JEM 2100, JEOL).

## Results and discussion

TEM images showed GroEL<sup>D52/398A</sup>/GroES complexes encapsulating several types of nanoparticles. In the absence of nanoparticles, holes of GroEL<sup>D52/398A</sup>/GroES were looked white. In contrast, nanoparticle encapsulating GroEL<sup>D52/398A</sup>/GroES caught black ~ gray colored dot in their cavities. Interestingly, GroEL<sup>D52/398A</sup>/GroES could encapsulate one FePt and two pt nanoparticles in each cavity of the complex (Fig. 1f). These results suggest GroEL<sup>D52/398A</sup>/GroES can encapsulate a variety types of nanoparticles (particle size ~10 nm).

**Fig. 1.** TEM images of metal nanoparticles encapsulated in the GroEL<sup>D52/398A</sup> football-shaped complex. (a) No nanoparticles, (b)  $\phi$  7 nm CdSe/ZnS, (c)  $\phi$  4 nm FePt, (d)  $\phi$  10 nm Au, (e)  $\phi$  5 nm Ag, (f) FePt and  $\phi$  2 nm Pt.

# The Yin-Yang Nature of Biologically Active Pterocarpanquinones: ROS Release and Alkylating Ability also Revealed by Electrochemistry

Marilia O. F. Goulart,<sup>a</sup> Thaissa L. Silva,<sup>a</sup> Camila C. de Vasconcelos,<sup>a</sup> Fabricia R. Ferreira,<sup>a</sup>  
Chaquip D. Netto,<sup>b</sup> Paulo R.R. Costa<sup>b</sup>

*Núcleo de Pesquisa em Recursos Naturais, UFRJ, Rio de Janeiro, Brazil*  
*mariliaofg@gmail.com*

LQB-118, a pterocarpanquinone, promotes apoptosis in *Leishmania amazonensis* promastigotes through the formation of ROS, which cause oxidative stress, mitochondrial membrane depolarization and DNA fragmentation <sup>[1]</sup>. Furthermore, it inhibited the proliferation and induced apoptosis in leukemic cells, via activation of caspases-3 <sup>[2]</sup>. The *para*-quinone moiety can participate in the redox cycle in the cell, acting as a precursor of ROS and leading to oxidative stress. Alternatively, LQB 118 can be activated in situ by reduction, leading to conjugated intermediates, which are powerful alkylating agents <sup>[1,2]</sup>. Some derivatives were synthesized and also submitted to biological assays.

We investigated the electrochemical behavior of LQB-118 and derivatives in aprotic media, in the absence and presence of oxygen in order to obtain data regarding its reduction mechanism, reactivity with oxygen, the analysis of the stability of the electrogenerated intermediate and interactions with biological targets, like DNA. An electrochemical cell with three electrodes was used: Ag/AgCl (KCl saturated) (reference), platinum wire (auxiliary) and glassy carbon as working electrode was used.

CV and DPV for LQB-118 and derivatives in aprotic medium (Figure 1) display, at least, 4 waves, the first two related to the usual reduction of the quinone moiety. The presence of additional waves suggests the cleavage of the heterocyclic rings and the generation of additional reducible systems <sup>[2]</sup>. Further, electrochemical experiments were carried out in the presence and absence of oxygen to verify the reactivity with oxygen, after the reduction of LQB-118, with positive results. Studies with dsDNA biosensor, in buffered aqueous medium showed no interaction between LQB-118 and reduction product with dsDNA after 15 min of contact, differently from the behavior in presence of ssDNA, in solution. The interaction with oxygen and the generation of ROS partly explains the cytotoxic action of the quinone in studied cancer cells. It is another case of successful pharmacoelectrochemical investigation. Further studies on substituted pterocarpanquinones will be also described. CNPq, CAPES, FAPEAL, INCT-Bioanalítica.

katarzyna.krukiewicz@polsl.pl

Local delivery is an innovative approach of medical treatment introduced to decrease the toxicity of therapeutics against healthy tissues by optimization of their concentrations during extended drug exposure time. This is of a significant importance when strong drugs, especially antibiotics and anti-cancer agents, are used. The concept of localized drug delivery may be realized by means of conjugated polymers – biocompatible, highly conducting materials able to undergo reversible redox reactions. In contrast to the physical entrapment, conjugated polymers allow highly controlled, reversible electrostatic immobilization of a wide range of biologically active compounds [1,2]. Change in their reduction-oxidation state as a result of electrical stimulation is followed by the release of a precise amount of drug [3].

Betulin is a naturally abundant triterpene significantly inhibiting viability in cervix carcinoma HeLa cells, lung adenocarcinoma A549 cells and breast cancer MCF-7 cells [4]. In this study, conducting poly(3,4-ethylenedioxypyrrole) matrix was used to serve as a nano-reservoir of disuccinyl derivative of betulin (Fig.1). The process of immobilization was realized with the use of electrochemical techniques, cyclic voltammetry and chronoamperometry. The efficiency of electrically-triggered release was studied in-situ by means of UV/Vis spectrophotometry. Raman spectroscopy and scanning electron microscopy were used to analyze structural and surface properties of polymer matrices.

Fig.1. Chemical structure of disuccinyl derivative of betulin.

Electrodeposited amorphous Iridium Oxide (EIROF) pertains to a class of highly hydrated transition metal oxides with a set of peculiar properties (e.g. low density), bound to their deposition conditions identifying the kinetically most accessible, rather than thermodynamically most stable, form [1].

Quite recently, EIROF was used as electrode material in a series of investigations centered on disclosing the mechanism of oxygen evolution reaction (OER) in combination with in-situ X-Ray Absorption techniques, by taking advantage of the high accessibility of its electrocatalytic sites [2,3]. In particular, it could be proved that for  $E > 1.3$  V (vs RHE), Ir assumes two distinct oxidation states, namely (III) and (V). This is in line with the participation of Ir sites, in the heterogeneous Ir oxide catalyst, to the catalytic cycle as well established for homogeneous catalysis and as described in the scheme and CV here below.

This effect comes not only from the easy accommodation of different oxidation states in IrOx nanoparticles [4], but also from the facilitated ionic transport within the hydrous oxide layer during electron and charge transfer processes.

In the present contribution the behaviour of electrodeposited EIROF nanoparticles, as observed by in-situ dispersive XAS in the pseudo-capacitance region at different pH's and for different polarisation steps, is presented and discussed.

# Electrochemical Surface-Enhanced Raman Microscopy (EC-SERM)

Bin Ren, Cheng Zong, Chanjun Chen, Meng Zhang

*State Key Laboratory of Physical Chemistry of Solid Surface, Collaborative Innovation Center of Chemistry of Energy Materials (iChEM), Department of Chemistry, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen 361005, China*  
E-mail: bren@xmu.edu.cn

Recent development of electrochemistry requires techniques with higher temporal and spatial resolution. Conventional electrochemical methods can only obtain the total current response of the electrode, which cannot fulfill the increasing request to detect the local electrochemical information. Scanning electrochemical microscopy is the most widely used electrochemical technique that is able to obtain the spatial electrochemical information of heterogeneous electrode surfaces. However, the point-scan mode limits its imaging rate. Recently, the combination of high resolution optical imaging techniques such as surface plasmon resonance, fluorescence and dark field scattering with electrochemical methods are receiving increasing interest. However, all these optical methods lack of molecular signature, which can hardly be used in a complex system containing multiple electrochemical active components due to the poor chemical identification and low selectivity.

To address the aforementioned challenges, we developed an electrochemical surface-enhanced Raman microscopy (EC-SERM), which allows us to simultaneously monitor the local electrochemical process with the fingerprint molecular information. We used the intensity of surface-enhanced Raman spectroscopy (SERS) signals of molecule of interest to deconvolute the local faradic current during cyclic voltammetric measurement. The method allowed us to simultaneously monitor the redox process of a mixture, Nile blue and viologen, on a Ag NPs electrode, and successfully reconstructed the independent electrochemical current of these two molecules. In addition, by using line-shape laser, we have been able to obtain the local electrochemical response at different position of the electrode surface. EC-SERM enables local electrochemical measurements with high spatial and temporal resolution, which will be particularly important for the investigation of non-uniform surfaces widely used in some energy-related electrochemical systems.

Kyoto University, Yoshida, Kyoto, 606 Japan  
uchimoto.yoshiharu.2n@kyoto-u.ac.jp

*operando* synchrotron X-ray analysis enables us to clarify the reaction mechanism at lithium ion cathode. In this study, *operando* techniques by using synchrotron X-ray method and its application to lithium battery cathode analysis using their measurement characteristics are demonstrated.

## 1. Dynamics of the phase transition behavior of cathode materials<sup>1-2)</sup>

*operando* analysis enables us to observe dynamic behavior occurring in an operating battery without touching its components and so actual processes associated with charging/discharging can be elucidated. Recently the measuring probes have been much improved and observation at practical charging/discharging rate to 50 C is now available. In this study, in situ techniques by using synchrotron X-ray method and its application to lithium battery analysis using their measurement characteristics are demonstrated.

The (dis)charge reaction of  $\text{LiFePO}_4$  proceeds through a two phase behavior between Li-rich  $\text{Li}_{1-x}\text{FePO}_4$  (LFP) and Li-poor  $\text{Li}_x\text{FePO}_4$  (FP). Phase transition mechanism is analyzed by time-resolved X-ray diffraction (TR-XRD) measurements at various temperatures. For  $\text{LiFePO}_4$  electrodes, we tracked the phase transition behavior under 1C rate charging conditions and figured out that there are various intermediate states between the LFP (discharged) and FP (charged) phases that have not been clarified with ex situ analysis.<sup>1)</sup> The smaller the particle size was, the greater the intermediate states changes until it reached to the thermodynamically stable FP phase. At much higher rate of 10 C, we found a new metastable crystalline phase “ $\text{Li}_x\text{FP}$ ”<sup>2)</sup>. This result shows that such a metastable phase can be a kinetically favorable intermediate when a strong motive force (large polarization) exists. Under high rate cycling, we revealed the formation of a metastable phase of  $\text{Li}_x\text{FePO}_4$  ( $x = 0.6\text{--}0.75$ ) ( $\text{L}_x\text{FP}$ ) which acts as a buffer layer between LFP and FP.<sup>2)</sup>

## 2. *operando* X-ray Absorption Spectroscopic Study on Stability at Electrode / Electrolyte Interface<sup>3-4)</sup>

Lifetimes of lithium-ion batteries are often affected by deterioration of positive electrodes. It is well-known that the deterioration of the positive electrodes can be reduced by using electrolyte additives; however, the mechanism underlying this cyclability improvement needs to be clarified. In this study, we investigate electronic structure at the electrode/electrolyte interface using in situ total-reflection fluorescence X-ray absorption spectroscopy to elucidate the mechanism underlying the cyclability improvement of a  $\text{LiCoO}_2$  electrode. We also clarify the effect of electrolyte addition of vinylene carbonate (VC) to the electrolyte. The results indicate that the reduction of cobalt ions at the surface of the  $\text{LiCoO}_2$  electrode, which occurs upon soaking in the electrolyte in the absence of VC, is suppressed by the presence of the VC additive. The VC additive also suppresses irreversible change in the electronic structure of the cobalt ions at the  $\text{LiCoO}_2$  surface during successive charge/discharge processes. The effects of the VC additive can be attributed to the formation of a layer of decomposed VC molecules at the  $\text{LiCoO}_2$ /electrolyte interface, which plays an important role in the suppression of the irreversibility at the  $\text{LiCoO}_2$  surface during the charge/discharge processes.

# Electrooxidation mechanism of NH<sub>3</sub> on Pt by in situ FTIR reflection spectroscopy

**Zhi-You Zhou\***, Yu-Hao Hong, Tian Sheng, Jian-Long Lin, Ji Ren, Sheng-Pei Chen, Shi-Gang Sun  
*State Key Laboratory of Physical Chemistry of Solid Surfaces, Department of Chemistry, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen 361005, China*

\*e-mail address: [zhouzy@xmu.edu.cn](mailto:zhouzy@xmu.edu.cn)

Ammonia contains high percentage of hydrogen, and is considered as a potential fuel molecule for fuel cells. Electrooxidation of ammonia on Pt surface is a complex reaction, since it involves a series of possible adsorbed species (NH<sub>2,ad</sub>, NH<sub>ad</sub>, N<sub>ad</sub>), and their couple to form N<sub>2</sub> finally. Although a general reaction mechanism has been proposed as early as 1970 by Gerischer and Mauzerer<sup>[1]</sup>, the spectroscopic evidences of adsorbates are very limitted.

In this presentation, I will talk about our recent studies about NH<sub>3</sub> electrooxidation on Pt by in situ FTIR spectroscopy. We used square-wave electrodeposition to prepare dendritic Pt nanostructure that shows high significantly enhanced infrared absorption for adsorbed species. On such dendritic Pt nanostructure, we successfully detected N-coupled adsorbed species (N<sub>2</sub>H<sub>x,ad</sub>), a key intermediate to form N<sub>2</sub> for NH<sub>3</sub> electrooxidation on Pt. The IR band of this species locates at ~1250 cm<sup>-1</sup> with a Stark tuning rate of 55 cm<sup>-1</sup> V<sup>-1</sup>, and <sup>14</sup>N-<sup>15</sup>N isotopic shift of 2 ~ 3 cm<sup>-1</sup>, indicating it is adsorbed species and contains N-H. DFT calculation shows that NH<sub>2,ad</sub> and NH<sub>ad</sub> have no vibration peaks near 1200 cm<sup>-1</sup>, but N<sub>2</sub>H<sub>x</sub> (x=2-4) species have vibration peaks between 1200 and 1300 cm<sup>-1</sup>. According to calculated free energy diagram of NH<sub>3</sub> oxidation on Pt(100), this species is likely to be N<sub>2</sub>H<sub>x</sub> (x=2, 4). In addition to adsorbed species, a series of solution species, such as N<sub>2</sub>, NO, N<sub>2</sub>O, and NO<sub>2</sub><sup>-</sup> were also detected by in situ FTIR spectroscopy and online electrochemical mass spectrometry (OLEMS). This study is of importance for understanding electrooxidation mechanism of NH<sub>3</sub>.

# In situ NMR for Electrochemistry

Eric G. Sorte, YuYe J. Tong  
Georgetown University, Department of Chemistry  
37<sup>th</sup> and O Streets NW, Washington DC 20057  
eric.sorte@georgetown.edu

We have developed two novel and potentially groundbreaking new *in situ* methodologies for applications of nuclear magnetic resonance (NMR) spectroscopy to the current research in the fields relevant to electrochemical (EC) energy generation (fuel cells) and storage (Li/Na/Al- ion batteries). NMR features unmatched chemical specificity and accessibility to most elements in the periodic table, and its exquisite technical versatility (i.e., non-invasiveness, applicability to various forms of matters, ability to see the buried interfaces, and access to both static and dynamic information) has made it the spectroscopic method of choice for studying many systems. However, technical incompatibilities between good NMR detection and the presence of conducting materials indispensable to electrochemistry have hampered efforts to apply the full power of NMR to investigations of EC systems. While a handful research groups have been constantly working in this niche of frontier research with well-known technical challenges,<sup>1,2</sup> the last decade has witnessed only incremental progress in the *in situ* applications of NMR to investigating fundamental chemical processes involved in the EC energy generation and storage. Both of our new methods of *in situ* EC-NMR lay the groundwork for bringing the entirety of NMR measurement and imaging power to investigations of electrochemical systems.

## 1. Interdigitated stripshield EC-NMR

The first method employs an **interdigitated electrode stripshield** design that can be realized in a rather straightforward fashion, and is ideal for measuring high-resolution liquid NMR during electrolysis in standard commercial facilities, as no modifications to commercially available NMR equipment is required. Identifying and quantifying electrocatalytic-reaction-generated solution species is highly desirable in terms of understanding the associated mechanisms of a given reaction. We report a straightforward implementation of *in situ* solution electrochemical <sup>13</sup>C and <sup>1</sup>H NMR spectroscopy that for the first time enables *in situ* NMR studies of catalyzed reactions during electrolysis. Using ethanol oxidation reaction (EOR) and bromoanthracene reduction as reaction examples, we demonstrate <sup>13</sup>C and <sup>1</sup>H NMR during electrochemical experiments using our interdigitated gold electrode stripshield EC-NMR design. In addition to demonstrating the feasibility and power of our system, we report new discoveries in EOR on Pt and PtRu black commercial catalysts using our new EC-NMR design.

## 2. Stripline EC-NMR

The second method is based on an **electrically floating stripline** detector, and is well suited to air-sensitive battery and supercapacitor research where the elements of interest are not necessarily in the liquid state. *In situ* NMR studies of metal-ion batteries are traditionally very challenging, and require the use of sophisticated and expensive equipment.<sup>3,4</sup> This EC-NMR design is intended to simplify and improve *in situ* NMR measurements on electrodes and electrolytes of Li, Na, or other metal-ion batteries. We present our design for the stripline EC-NMR probe and demonstrate its utility and simplicity in battery measurements. We show also the feasibility of multi-pulse experiments, which may allow for *in situ* imaging of the storage devices during operation. This method allows the observation and quantification of the growth of metallic microstructures (which can cause short circuits and battery failure), and can be utilized to identify conditions that promote malicious dendrite formation.

The lithium–oxygen (Li–O<sub>2</sub>) battery has suffered from huge charge polarization ( $> 4.0$  V) due to sluggish oxidation of insulating Li<sub>2</sub>O<sub>2</sub> ( $2\text{Li}^+ + \text{O}_2 + 2\text{e}^- \rightleftharpoons \text{Li}_2\text{O}_2(\text{s})$ ), which accompanies degradation of electrolyte solution and carbonaceous electrode.[1, 2] Understanding the decomposition process of Li<sub>2</sub>O<sub>2</sub> is therefore of important to circumvent low round-trip efficiency in the Li–O<sub>2</sub> battery. However, there is little knowledge for detailed oxidation process. Here, we present *in situ* imaging observation of Li<sub>2</sub>O<sub>2</sub> decomposition during oxidation using electrochemical atomic force microscopy (ECAFM). In a Li–O<sub>2</sub> model cell, highly oriented pyrolytic graphite (HOPG) was used as the working electrode in an O<sub>2</sub> gas-saturated glyme-based electrolyte, which was performed with metallic lithium as the counter and reference electrodes.[3] The AFM probe scanned the surface of HOPG during potential-controlled reduction and oxidation process. During reduction, the Li<sub>2</sub>O<sub>2</sub> film is uniformly formed with  $\sim 3$  nm thickness at 2.2 V (vs. Li/Li<sup>+</sup>). The subsequent oxidation was conducted via anodic linear sweep voltammetry (LSV) at a potential sweep rate of 0.2 mV/s or 0.5 mV/s.

The oxidation process can be separated to two distinct processes at low-potential ( $< \sim 3.7$  V) and high-potential ( $\sim 3.7$ – $4.5$  V) regimes. In the low-potential regime, slow decomposition occurs from thinner spots of Li<sub>2</sub>O<sub>2</sub> film, which results in sparse holes on the film. Further decomposition takes place at the edge of holes. However, its sluggish process restricts the decomposition at local spots, which cannot propagate to the entire Li<sub>2</sub>O<sub>2</sub> film. At the high potential, bulk decomposition of Li<sub>2</sub>O<sub>2</sub> occurs. The total thickness Li<sub>2</sub>O<sub>2</sub> film is promptly decreased and the film completely disappears at  $\sim 4.2$  V.

The high potential required for the bulk oxidation can be curtailed by the addition of a redox mediator. Representatively, the redox mediator of TEMPO ((2,2,6,6-tetramethylpiperidin-1-yl)oxyl)[4] in electrolyte solution is oxidized to TEMPO<sup>+</sup> at a potential of 3.75 V (vs. Li/Li<sup>+</sup>), which then functions as electron acceptor thus chemically triggering the decomposition of Li<sub>2</sub>O<sub>2</sub>. By using the ECAFM imaging during anodic LSV at 0.2 mV/s, we observe that the Li<sub>2</sub>O<sub>2</sub> film is completely decomposed at around 3.76 V with 10 mM of TEMPO, demonstrating decrease in bulk-oxidation potential and fast electron-transfer reaction between TEMPO<sup>+</sup> and Li<sub>2</sub>O<sub>2</sub>. Detailed ECAFM study of Li<sub>2</sub>O<sub>2</sub> decomposition process at the low- and high-potential regimes will be discussed in the presentation.

**Figure 1.** *In situ* ECAFM images obtained (a) after reduction at 2.2 V, and (b–d) during anodic LSV at 0.2 mV/s sweep rate. Blue arrows indicate AFM scanning direction. Topography and phase images cover the contrast in the range of 5 nm and 1 deg, respectively.

# Multi-scale tomographic analysis of fuel cells, batteries and electrolyzers

*Simon Thiele, Lukas Zielke, Riko Moroni, Severin Vierrath, Matthias Klingele and Roland Zengerle*  
Laboratory for MEMS Applications, IMTEK - Department of Microsystems Engineering, University of  
Freiburg Address: Georges-Köhler-Allee 103, 79110 Freiburg, Germany  
e-mail address: [simon.thiele@imtek.de](mailto:simon.thiele@imtek.de)

Electrochemical systems such as batteries, fuel cells, or electrolyzers typically exhibit performance-relevant morphological features on different length scales (e. g. nano and micro porosity in battery electrodes, Figure 1 A) [1–3]. Imaging on these length scales is covered by various tomographic techniques, such as X-ray tomography (Xt), focused ion beam / scanning electron microscopy tomography (FIB/SEMt), transmission electron microscopy tomography (TEMt) and atom probe tomography (APT) (Figure 1 B).

*Figure 1 A) Top-down images of the three-phase configuration of a  $\text{LiCoO}_2$  battery electrode (X-ray tomogram and two scales of FIB-SEM imaging). Each imaging approach reveals different morphological features of the battery. B) shows lateral resolution (x- and y-direction) and z-resolution of various tomographic approaches. For a specific resolution only a limited number of tomographic methods can be used.*

For hierarchical structures on multiple length scales, the use of different tomographic approaches is usually necessary, resulting in multi-scale analysis. However, a variety of challenges arises with the use of tomographic approaches: i) Transport parameter calculation is not straight forward, as physically correct solvers are often either not available or too costly by means of calculation time. ii) The validation of results obtained by tomographic imaging is essential to enable correct interpretation. In many cases, this can solely be performed virtually by inverse approaches (e.g. [4]). iii) To combine information from different length scales, additional tools are necessary (e. g. spatio-statistical modeling [1]).

Within this talk, multi-scale tomographic approaches and challenges for various electrochemical systems are discussed: i) For Lithium-metal-oxide electrode reconstruction we show that multi-scale approaches are necessary if transport parameters extracted from tomographic reconstructions are supposed to be meaningful. ii) For polymer electrolyte membrane (PEM) fuel cells we demonstrate that multi-scale reconstruction is not only important for the whole cell, but also already for their individual components, such as catalyst layers. iii) For PEM electrolyzers, we show first results for tomographic reconstructions and place emphasis on the importance of future works on multi-scale reconstruction.

# A Long Duration Experiment Facility for the Study of Battery Materials Using In Situ Synchrotron X-Ray Powder Diffraction

Sarah Day<sup>1</sup>, Annabelle Baker<sup>1</sup>, Chiu Tang<sup>1</sup>, Claire Murray<sup>1</sup>, Stephen Thompson<sup>1</sup>

<sup>1</sup>*Diamond Light Source*

*Harwell Science and Innovation Campus, Didcot, Oxfordshire, OX11 0DE*

[sarah.day@diamond.ac.uk](mailto:sarah.day@diamond.ac.uk)

The use of in-situ X-Ray Powder diffraction for the study of new battery materials has grown in recent years and has proven to be an extremely useful technique for the in operando study of new battery materials, providing an insight into the complex processes that take place during charge/discharge cycling. Typical in situ experiments using existing facilities are, however, often limited to short periods of time, from a few hours up to a few (2-3) days, and therefore only allow one long cycle or multiple very fast cycles to be observed. The result is that the material characteristics may be well understood for the first cycle but little is known about the long term processes that ultimately lead to failure of the cell over longer timescales.

The Long Duration Experiment (LDE) Facility on Beamline I11 at Diamond Light Source (UK) is the first of its kind, housing experiments that require periodic, in-situ monitoring over periods of months to years. With a specially designed coin cell holder (right) and a dedicated multi-channel battery charger, it is an ideal facility for the long term study of both existing and next generation battery materials. This setup allows data to be collected over many hundreds of cycles at more realistic rates, without the need for accelerated cycling, therefore better simulating battery use under real-life conditions.

Previous in-situ diffraction experiments of battery materials have generally involved using unconventional battery cells - loading battery materials into capillaries or Swagelok cells, for example, and while these are effective and excellent for fundamental research, they are not real batteries and are not desirable for long duration experiments. We have therefore modified standard coin cells to allow the transmission of X-rays, while also remaining impermeable to air and moisture for long periods of time. Preliminary data from the modified cells, confirming their suitability for long duration, in-situ experiments will be presented, along with further details of the LDE facility and its suitability for the study of battery materials.

# From Quantitative Differential Electrochemical Mass Spectrometry Experiments to Electrochemical Surface Reaction Models

Fabian Kubannek, Ulrike Krewer

TU Braunschweig

Franz-Liszt-Str. 35, Braunschweig, Germany

f.kubannek@tu-braunschweig.de, u.krewer@tu-braunschweig.de

Understanding the micro- and makrokinetics of electrochemical reactions in detail is essential for the development, model-based analysis, and optimization of electrocatalysts and devices such as fuel cells and batteries. Physical modelling is a tool which is often employed to better understand reaction kinetics and determine rate constants by fitting model parameters to experimental data. However, since physical models often require numerous parameters to be determined, monitoring potential and current only – for example during a CV – provide only restricted insight and limited reliability of the fitted parameters. In this work we present how to produce more reliable quantitative models of electrochemical surface reactions by using Differential Electrochemical Mass Spectrometry (DEMS) to monitor in situ not only electric quantities but also product and intermediate formation rates.

Quantitative modeling and analysis of reaction kinetics requires to minimize response times of the DEMS. Moreover, the reactant flow within the electrochemical cell and the concentration distribution over the electrode need to be defined and well-known so that mass transfer effects can be taken into account. We designed a new cell, a DEMS cyclone flow cell, for quantitatively detecting products of electrochemical reactions with a low response time.

The newly designed cell features a well-defined flow regimen and response times of well below one second, enabling dynamic DEMS measurements. While quantitative DEMS studies in the past (eg. [1]) have mostly assessed conversion efficiencies for different products in steady state or during CVs at low scan rates we combined for the first time dynamic measurements such as potential step response measurements and impedance techniques with DEMS to better resolve different timescales.

The new cyclone flow cell and the DEMS setup are presented along with calibration results, and the influence of reactant concentration on the calibration constants for reaction products is analyzed. In order to extract kinetic data from measurements, mass transfer and kinetic effects need to be separated. Thus, the concentration distribution in the cell is analyzed closely. CFD simulations and experimental analysis of electrolyte flow and mass transfer in the cyclone flow cell are presented. We obtain a nearly homogeneous concentration boundary layer over 75% of the electrode surface and demonstrate how to use this information to set up a physical model that describes the concentration in the concentration boundary layer. The physical model furthermore contains differential equations for the surface coverages of adsorbed species, adsorption and desorption steps as well as reaction steps. Rate constants are obtained by fitting simulated faradaic currents and product formation rates to measured currents and DEMS data using the oxidation of small organic molecules as example reactions.

Our work expands the scope of DEMS to dynamic measurements and opens up a way to fit model parameters more reliably to experimental data by in situ monitoring of product formation rates. Thus, our approach provides a valuable tool for analyzing reaction kinetics, setting up and parameterizing physical models, and determining rate constants.

# In-situ $^{13}\text{C}$ NMR spectroscopy study of ethanol electro-oxidation on Pt and PtRu

Long Huang,<sup>ab</sup> Eric G. Sorte,<sup>b</sup> YuYe Tong<sup>\*b</sup> and Shi-gang Sun<sup>\*a</sup>

<sup>a</sup>Departments of Chemistry and State Key Laboratory for Physical Chemistry of Solid Surfaces, Xiamen University, Xiamen 361005, P. R. China. E-mail: [sgsun@xmu.edu.cn](mailto:sgsun@xmu.edu.cn)

<sup>b</sup>Department of Chemistry, Georgetown University, 37th & O Streets,NW, Washington, DC 20057, USA. E-mail: [yyt@georgetown.edu](mailto:yyt@georgetown.edu)

Nuclear magnetic resonance (NMR) spectroscopy is powerful in identifying and quantifying chemical species, especially for those containing carbon and hydrogen atoms, and is prevalingly used in organic chemistry. However, it has rarely been applied to electrochemistry due largely to the intrinsic incompatibility between NMR detection coil and the electrical conduction necessary for electrochemical reactions. Recently, Dunsch et al. studied electrochemical redox reaction by acquiring in-situ sampling  $^1\text{H}$  NMR spectra through designing a novel combined electrochemical-NMR (EC-NMR) cell configuration and adopting carbon fiber as working electrode.<sup>[1]</sup>

By slightly modifying the Dunsch's configuration, we carried out, for the first time, an in-situ  $^{13}\text{C}$  NMR spectroscopic study of ethanol electrooxidation reaction (EOR). An ampule containing a known amount of  $^{13}\text{C}$ -label octanethiol was used as an internal reference for quantitative analysis. The position of the carbon fiber with respect to the NMR detection coil is critical to the NMR measurements. Placing the end the carbon fiber just above the detection coil was found to be the best compromise between NMR detection and electrochemical operation. By physical deposition of commercial (Johnson Matthey) platinum black (Pt black-JM) and platinum ruthenium black (PtRu black-JM) onto the carbon fiber, EOR at 250mV vs a Ag/AgCl wire was followed by  $^{13}\text{C}$  NMR over a period of 24 hours during which the spectra were recorded with a time interval of 1 hour before and of 2 hours after 8-hour mark. The peak at 58ppm is assigned to carbon atoms bound to the hydroxy group of ethanol, which diminished as the EOR continued, indicating a consumption of ethanol. Simultaneously, acetic acid ( $\text{CH}_3^*\text{COOH}$ ) at 177ppm and acetaldehyde ( $\text{CH}_3^*\text{CHO}$ ) at 208ppm were detected respectively. By quantitative analysis of the time-resolved  $^{13}\text{C}$  NMR spectra recorded during EOR on Pt black and PtRu black, we discovered that (1) the complete oxidation of ethanol to  $\text{CO}_2$  only took place dominantly at the very beginning of a potentiostatic chronoamperometric (CA) measurement, and (2) the PtRu black has a much higher activity in catalyzing oxygen insertion reaction that leads to acetic acid.

**Acknowledgements.** This work was supported by NSFC (21229301 and 21321062), DOE-BES (DE-FG02-07ER15895), Xiamen University Graduate School and Georgetown College and graduate School.

# ***In-situ* identification of electrochemical oxidation of Pt(111) and Pt(100) by Raman spectroscopy assisted by DFT calculation**

Yi-Fan Huang and Marc T. M. Koper

*Leiden Institute of Chemistry, Leiden University, Einsteinweg 55, P.O. Box 9502, 2300 RA Leiden, The Netherlands*

*E-mail: y.huang.13@chem.leidenuniv.nl*

Towards the fundamental understanding of the mechanism of degradation of Pt catalysts in electrochemical oxygen reduction reaction, we employed *in-situ* shell-isolated nanoparticles-enhanced Raman spectroscopy to identify the intermediate stages of the electrochemical oxidation of Pt(111) and Pt(100) single crystal at the molecular level. DFT calculations were carried out to assist in assigning the experimental Raman spectra by simulating the vibrational frequencies of possible intermediates and products.

Figure 1a represents a cyclic voltammogram of Pt(111) in 0.1 mol/L HClO<sub>4</sub> electrolyte. The oxidation of Pt(111) can be divided into different three stages, according to the characteristic peaks. Figure 1b shows typical Raman spectra acquired in these stages. A single band with a frequency of 922 cm<sup>-1</sup> can be seen at 0.8 V, whose frequency is closed to that of symmetric stretching of Cl-O of ClO<sub>4</sub><sup>-</sup>. Thus, the adsorption of ClO<sub>4</sub><sup>-</sup> appears to be involved in the formation of OH species on surface at the potential span between 0.5 V and 0.9V. When the potential is stepped to 1.0 V, the bands at 240 cm<sup>-1</sup>, 956 cm<sup>-1</sup> and 1169 cm<sup>-1</sup> replace the stretching of Cl-O. To the best of our knowledge, this is the first report of these bands. Thus, we relied on the DFT calculation of possible surface species. We found the superoxo-like species represent quite similar vibration frequency of stretching modes of O-O and Pt-O (not shown), as shown in figure 1c. It has been found the Raman intensity stretching mode of O-O is usually strong. Therefore, we propose a superoxo-like 2D surface oxide form at the potentials between 1.0 V and 1.2 V. At the potentials above 1.3 V, a new broad band at *ca.* 600 cm<sup>-1</sup> appears. According to the normal Raman spectra of PtO<sub>2</sub> and hydrated PtO<sub>2</sub>, the new band can be assigned to the amorphous 3D PtO<sub>2</sub> species. Our measurements elucidate the entire process of the electrochemical oxidation of Pt single crystals corresponding to cyclic voltammogram. We will include results and discussions on Pt(100) and polycrystalline Pt.

Figure 1 a) Cyclic voltammogram of Pt(111) in 0.1 mol/L HClO<sub>4</sub>; b) Potential dependent Raman spectra of Pt(111) covered by Au@SiO<sub>2</sub> nanoparticles in 0.1 mol/L HClO<sub>4</sub>; c) Superoxo-like surface oxide on Pt(111) surface simulated by DFT calculation.

# Complementary operando XPS and Raman spectroscopy of graphite cycled in ionic liquids

D. Streich, P. Novák, M. El Kazzi  
 Paul Scherrer Institut, Electrochemistry Laboratory,  
 CH-5232 Villigen PSI, Switzerland  
 mario.el-kazzi@psi.ch

It was recently demonstrated that the reversibility of the graphite cycling is significantly improved in presence of bis(fluorosulfonyl)imide ([FSI]<sup>-</sup>) [1]. In order to understand the origin of this beneficial effect, Raman [2] and XPS [3] analyses were employed as two complementary operando techniques to monitor structural changes in the bulk and the evolution of the chemical surface composition, respectively. Graphite particles and HOPG were used as model electrodes for Raman and XPS, respectively. These were cycled in 1-ethyl-3-methylimidazolium / bis(trifluoromethanesulfonyl)imide ([EMIM][TFSI]) ionic liquid electrolyte with either 1 M LiTFSI or 1 M LiFSI salt. The Raman outcomes show that [EMIM]<sup>+</sup> competes strongly with Li<sup>+</sup> for intercalation sites in graphite so that Li<sup>+</sup> intercalation only takes place at a detectable level in presence of [FSI]<sup>-</sup> (Figure 1.a). The in situ XPS measurement at the interface IL/electrode indicates that both [TFSI]<sup>-</sup> and [EMIM]<sup>+</sup> undergo reductive decomposition reactions during cycling and form a solid surface layer (Figure 1.b). Based on these results a model describing the mechanism behind the cycling improvement in presence of FSI<sup>-</sup> will be presented.

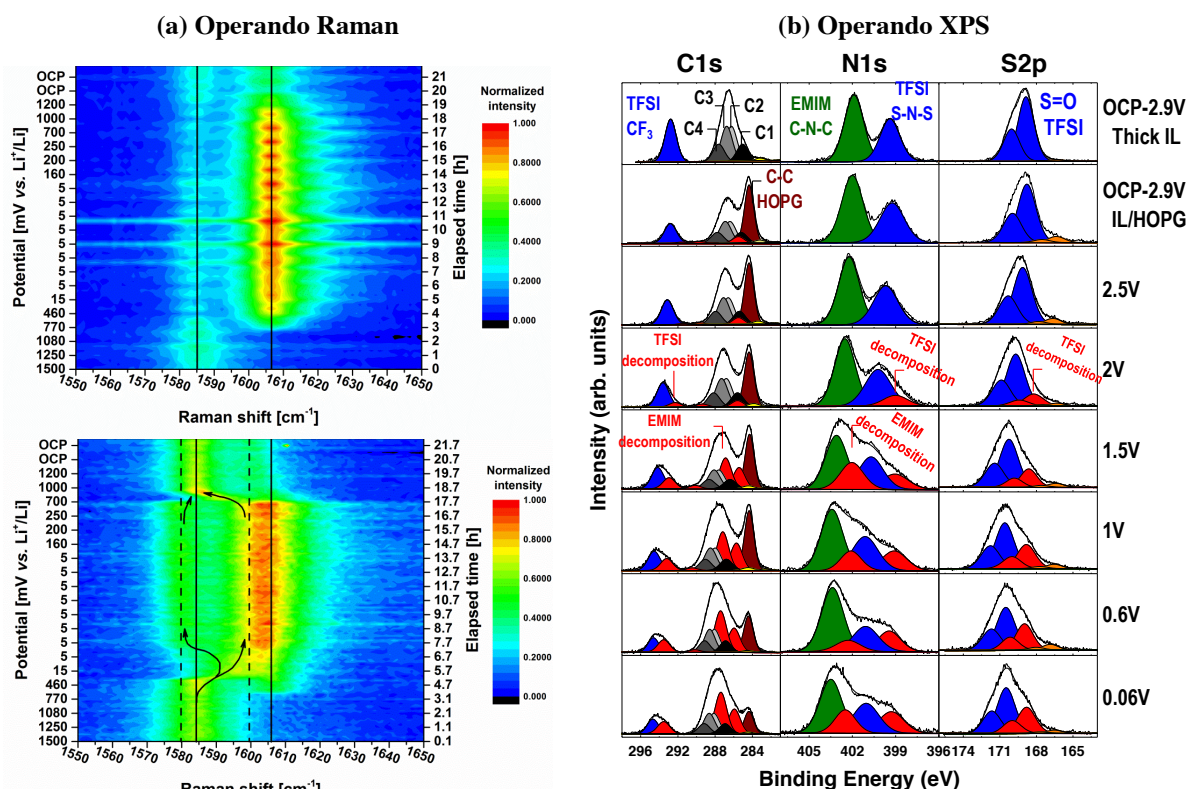

Figure 1: (a) Operando Raman characterization of a graphite particle cycled in discrete potential steps against Li metal in 1 M LiTFSI / [EMIM][TFSI] (top) and 1 M LiFSI / [EMIM][TFSI] (bottom). (b) Operando XPS spectra acquired at the interface electrolyte/electrode during the first reduction of HOPG against Li metal in 1 M LiTFSI / [EMIM][TFSI].

# The time and current-resolved evolution of sodium location and distribution in electrodes of sodium-ion batteries

Neeraj Sharma

UNSW Australia

School of Chemistry, UNSW Australia, Sydney NSW 2052 Australia

[Neeraj.sharma@unsw.edu.au](mailto:Neeraj.sharma@unsw.edu.au)

Electrochemical energy storage devices in the form of batteries are ubiquitous in society providing portable power solutions. There is a continuous drive for the improvement of batteries. A large proportion of the function of batteries arises from the electrodes, and these are in turn mediated by the atomic-scale perturbations or changes in the crystal structure during an electrochemical process (e.g. battery use). Therefore, a method to both understand battery function and improve their performance is to probe the crystal structure evolution *in situ* or *operando* - while an electrochemical process is occurring inside a battery.

Our work has used the benefits of *in situ* X-ray diffraction to probe structural-electrochemical evolution of different batteries types, such as primary lithium and ambient temperature rechargeable sodium-ion batteries. For sodium-ion batteries we are able to literally track the time-resolved evolution of sodium in cathode materials such as  $\text{Fe}[\text{Fe}(\text{CN})_6]_{1-x} \cdot y\text{H}_2\text{O}$ ,  $\text{FeCo}(\text{CN})_6$ , and  $\text{Na}_3\text{V}_2\text{O}_{2x}(\text{PO}_4)_2\text{F}_{3-2x}$  (Figure 1). In these systems, we have been able to directly relate electrochemical properties such as capacity, battery history, electrolyte influence and asymmetry in the charge/discharge potential profiles to the content, distribution and evolution of sodium in the cathode crystal structure.

**Figure 1.** Evolution of the occupancy of the Na(1) (red circles) and Na(2) (black squares) sites and total sodium content (blue triangles) in  $\text{Na}_3\text{V}_2\text{O}_{2x}(\text{PO}_4)_2\text{F}_{3-2x}$   $x = 0.8$ . Shaded regions are two phase regions.

Additionally, we have used neutron diffraction which shows good sensitivity towards lithium, to probe the evolution of electrodes in rechargeable lithium-ion batteries. Again, we are able to track lithium evolution during battery function (Figure 2).

**Figure 2.** A (left) selected reflection of the cathode (dark red) evolving as a function of time, correlated to the charge and discharge process in the battery. Snapshots (right) of the cathode crystal structure at various potentials during charge. Lithium is shown in green with shading indicating lithium occupancy and  $\text{MnO}_6$  octahedra are purple.

*In situ* experiments that probe the time-resolved structural evolution during charge/discharge provide unparalleled insight into how electrodes evolve. Using this information a comprehensive atomic-scale picture of battery functionality can be created and permutations can be made to the electrodes that optimize battery performance. This talk will showcase some of our recent results on electrode structural evolution with respect to electrochemistry in fully functioning batteries.

# Investigation of Solid Electrolyte Interface of Silicon Electrode in Li-ion Batteries by Dual-Electrode Scanning Probe

Chen-Yuan Lu(盧鎮遠), Yu-Lun Cheng(鄭毓倫), Bernard HaoChih Liu(劉浩志)<sup>†</sup>

Department of Materials Science and Engineering, National Cheng Kung University, Taiwan

<sup>†</sup> Corresponding author, Tel : (06)2757575#62926 ; E-mail address: [hcliu@mail.ncku.edu.tw](mailto:hcliu@mail.ncku.edu.tw)

Silicon electrode in Li-ion batteries is an attractive material because of its high theoretical specific capacity ( 4200 mAh/g ) as compared to that of the commercial graphitic carbons ( 372 mAh/g ). However, the large charge-discharge volume change of silicon makes it very challenging to form a stable solid electrolyte interface (SEI), whose stability has strong influence on the cycle life of Li-ion battery.. As it is difficult to observe *in-situ* status of SEI, a new method to characterize and analyze the condition of SEI is very much desired. In this study, we have developed a dual-electrode scanning probe (DESP) by microfabrication (Fig. 1). The two probes of DESP confine the electric current on the surface of silicon electrode. We also combined the micromanipulators and the electrochemical impedance spectroscopy (EIS) to establish *in-situ* measurement of the microscopic electrical property of SEI on the silicon electrode (Fig. 2). The DESP can measure the impedance in a single particle due to the micro scale of this special probe. With different degree of discharge time and charge-discharge cycles, the EIS results can help us to understand the forming mechanism of SEI on the Si electrode in more detail (Fig.3).

**Keywords:** silicon electrode, solid electrolyte interface, dual-electrode scanning probe, electrochemical impedance spectroscopy, microscopic electrical property, in situ

\*E-mail: [hardwick@liverpool.ac.uk](mailto:hardwick@liverpool.ac.uk); \*E-mail: [cchu@che.nthu.edu.tw](mailto:cchu@che.nthu.edu.tw);

Cation effects on the phase transformation and redox retention of  $\alpha$ -Ni(OH)<sub>2</sub> are demonstrated through the electrochemical quartz crystal microbalance (EQCM) and *in situ* Raman spectroscopy in LiOH, NaOH, and KOH.  $\alpha$ -Ni(OH)<sub>2</sub> was synthesised by cathodic deposition. From the literature [1,2], the redox mechanism of  $\gamma$ -NiOOH/ $\alpha$ -Ni(OH)<sub>2</sub> involves alkali and hydroxyl ions intercalation/de-intercalation, while  $\beta$ -NiOOH/ $\beta$ -Ni(OH)<sub>2</sub> only involves proton. Mass change (Fig. 1) related to cation intercalation can be clearly observed in LiOH for 10 cycles, while in KOH, it involves proton during the charge/discharge process. The strong A<sub>1g</sub> mode around 3580 cm<sup>-1</sup> is the signature of  $\beta$ -Ni(OH)<sub>2</sub>. *In situ* Raman spectra (Fig. 2) demonstrated the fast phase transformation from  $\alpha$ -Ni(OH)<sub>2</sub> to  $\beta$ -Ni(OH)<sub>2</sub> in KOH. The order of cations with respect to inducing the phase transformation is: K<sup>+</sup> > Na<sup>+</sup> > Li<sup>+</sup>. Due to the unstable  $\gamma$ -NiOOH structure with insufficient intercalated K<sup>+</sup>, the rapid phase transformation to a predominant phase of  $\beta$ -Ni(OH)<sub>2</sub> with severe structure deformation is obtain in KOH. In LiOH, Li<sup>+</sup> forms a larger size of hydrated ion in  $\gamma$ -NiOOH structure, which retains the water molecules in the inter-slab space to perform  $\gamma$ -NiOOH/ $\alpha$ -Ni(OH)<sub>2</sub> redox reaction. This work emphasizes the important electrolyte design for Ni(OH)<sub>2</sub> in its wide range of applications; e.g., the rechargeable batteries, supercapacitors, oxygen reduction reaction, and electrochromic devices.

Fig. 1 EQCM  $\Delta m$  - E curves of  $\alpha$ -Ni(OH)<sub>2</sub> in 1 M (a) LiOH and (b) KOH for 10 cycles at 10 mV s<sup>-1</sup> after 10 preceding cycles at 5 mV s<sup>-1</sup>.

Fig. 2 *In situ* Raman spectra recorded after (a) 10 and (b) 150 CV cycles at 10 mV s<sup>-1</sup> in LiOH, NaOH, and KOH.

One appealing form of integrated energy storage is the use of H<sub>2</sub>/air, a so-called fuel cell type (FC) battery. Such devices promise very high volumetric energy densities of more than 2000 Wh/l. Consequently, this type of battery has recently attracted more attention and primary as well as secondary cells have been realized. Oxygen reduction reaction (ORR) is an important process on the cathode of polymer electrolyte fuel cells [1]. ~~Particularly interesting is employing an alkaline polymer electrolyte fuel cell which brings the possibility to use non-noble metals as catalysts. Pickrahn et al. have used active MnO<sub>2</sub> electrocatalysts prepared by atomic layer deposition (ALD) for OER and ORR and oxygen evolution reaction (OER) [2].~~ Further improvements for these kinds of fuel cells have to be reached with respect to high power.

To this end, a promising approach is to increase the skin surface of porous chromium decorated nickel electrodes for enhancement of exchange current density by forming three-dimensional (3D) microstructures directly into the electrode. A novel laser structuring process was applied using ultrashort laser pulses. Ultrashort laser processing of complex multi-material systems for energy storage allow for precise material removal without changing the material properties. By applying this novel laser-based structuring technique, 3D microstructures could be formed permitting shortened diffusion lengths between the electrolyte and the electrode surface being necessary for increased exchange current densities (see Fig. Figure 1-1 Fig.1). The catalytic activity determines the exchange current density which is limiting factor of the whole cell performance. Modelling of the reactive surface at the atomistic scale is essential for understanding the effects of Cr on catalytic activity and optimizing the device function. Nevertheless, constructing adequate atomistic models for the oxygen reduction reaction on the cathode requires ~~determination of that~~ the composition, i.e. the amount and distribution of Cr on the surface and/or in the topmost layers at the surface, as well as ~~elucidation of~~ the structure of the surface ~~have to be elucidated~~. In this contribution, we combine x-ray photoelectron spectroscopy (XPS) data ~~of from the~~ experimental investigations of the Cr-modified Ni electrode with core-level shifts computed using density functional theory in order to estimate the amount and ~~determine the chemical~~ oxidation state of Cr on the catalyst surface, and ~~thus~~ develop atomistic models commensurate with the distribution of Cr on the surface and in the topmost atomic layers. In addition, the XPS data allow estimates of the locations and surface coverage by atomic oxygen. Amount of surface atomic oxygen O is known to be important not only for the catalytic activity but also for the stability of the electrode. These data enable modelling of the reaction rates under cell operating conditions which in turn allows deriving a design strategy for cell performance enhancements and creates an essential bridge between theory and experiment.

Sn-based material with higher theoretical capacity than commercial graphite has been seen as a potential material used in lithium-ion battery application. However, it suffers from huge capacity fading during the cycling due to its large volume expansion while lithium inserts/extracts. In order to overcome this problem, many efforts have been reported[1], such as porous/hollow structure and nano-composite, which could play a role as buffer zone and maintain its own structure. Recently, the synthesis of hollow cubic SnO<sub>2</sub> has been developed and effectively reduce the capacity fading of SnO<sub>2</sub>. [2] It is interesting to understand its mechanism for the capacity retention. Many characterization techniques have been intensively used to probe the structure change of SnO<sub>2</sub>, such as XRD, SEM and TEM. However, the study on the shape transformation of lithiated SnO<sub>2</sub> is still difficult to access. Synchrotron-based Transmission X-ray Microscopy (TXM) could be an useful tool to directly observe the shape change. [3]

The hollow cubic SnO<sub>2</sub> has been synthesized by selective leaching method[2]. SEM image of hollow cubic SnO<sub>2</sub> is shown in Figure 1(a), uniform hollow cubic SnO<sub>2</sub> could be observed and the average size of the cubic is around 2  $\mu\text{m}^3$ . Meanwhile, those particles are observed by TXM, shown in Figure 1(b), an image of square with black frame and white center has been obtained and the average size of the square frame is also around 2  $\mu\text{m}^3$  as well. This result indicates the cubic is hollow with the wall thickness around 300 nm. The various lithiated state of hollow cubic SnO<sub>2</sub> has also been studied. It could be found that as the lithium content increases, the size of the cubic enlarges but still remains in its cubic shape.

Figure 1. (a) SEM image and (b) TXM image of hollow cubic SnO<sub>2</sub>

The cycling performance of composite LIB electrodes is strongly influenced by the significant dimensional changes (deformation) of the electrode material during reversible lithium ion intercalation and deintercalation. [1, 2]. Typical LIB composite cathodes are composed of an active material with conductive additives and a polymeric binder. [you can add here your Adv. Energy Mat. paper?] Lithium manganese oxide (LMO) is a commercial grade active material with its inexpensive synthesis and a long lifetime.[3, 4] Until recently, dimensional changes in intercalation-type electrodes such as LiFePO<sub>4</sub> were characterized by quartz-crystal microbalance measurements assuming that the polymeric binder remains in its completely rigid form during cycling [5,6] However, dimensional changes in the active material apply stress on the binder which reacts with a strain dependent on its viscoelastic properties. [1] Here we combine a non-invasive in-situ monitoring of the dimensional changes via electrochemical quartz-crystal microbalance with dissipation monitoring (EQCM-D) [1] and electrochemical dilatometry.[6]

The monitoring of elastic properties of three different polymeric binders, namely polyvinylidene fluoride (PVdF), polytetrafluoroethylene (PTFE), and sodium carboxymethylcellulose (Na-CMC), was carried out in an aqueous electrolyte (0.1 M LiSO<sub>4</sub>) and in an aprotic electrolyte (1 M LiPF<sub>6</sub> in EC/DMC 1:1). While monitoring EQCM-D response from single/a few layer thick intercalation particles translated by a hydrodynamic admittance model [5] to average changes of the geometric characteristics of the composite electrode layer [1, 6] this information is supplemented by dilatometric measurements in the same electrodes of significantly larger thickness. In this way, we can track an average effect of the whole bulk electrode, which results in dimensional changes less than 1 % for rigid binder types and more than 10 % for soft ones. We find the combination of both, EQCM-D and dilatometry, as a unique tool to track the structural behavior of the binder in-situ and non-invasive during intercalation and deintercalation of Li ions into LMO composite electrodes.

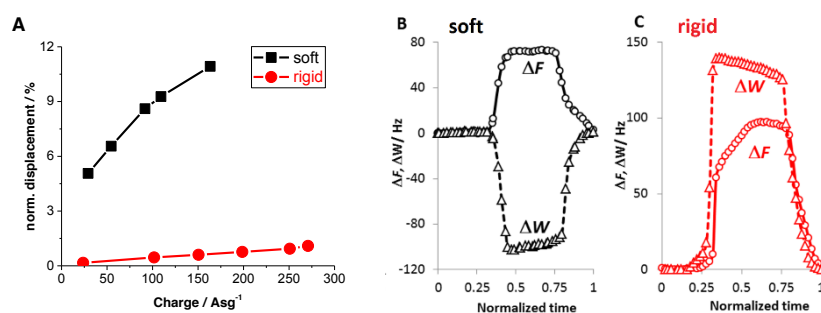

Figure 1: Different behavior of soft and rigid binder types in aqueous and non-aqueous electrolytes. (A) Dilatometry measurements shows varied expansion with soft or rigid binder and (B)+(C) EQCM-D data shows different change in frequency shift and dissipation.

# ***In situ* and *ex situ* NMR observation of delithiation/lithiation behavior of $\text{LiNi}_{0.5}\text{Mn}_{1.5}\text{O}_4$**

Keiji Shimoda, Miwa Murakami, Hideyuki Komatsu, Hajime Arai, Yoshiharu Uchimoto, Zempachi Ogumi

Lithium ion rechargeable batteries (LIBs) have been widely used as a power source for portable devices and now are available for applications to electric vehicles (EVs), which demand high-power, high-energy, inexpensive and safe batteries. A nickel-substituted lithium manganese spinel  $\text{LiNi}_{0.5}\text{Mn}_{1.5}\text{O}_4$  has been extensively studied as a preferred candidate of high-voltage positive electrode materials because it shows a wide potential plateau at  $\sim 4.7$  V vs.  $\text{Li/Li}^+$  with a theoretical capacity of 146.7 mAh/g. This material shows two distinct cubic structures depending on the Ni and Mn distribution. In the Ni/Mn ordered structure,  $\text{Ni}^{2+}$  and  $\text{Mn}^{4+}$  ions occupy the  $4b$  and  $12d$  Wyckoff positions in the space group  $P4_332$ , respectively, while these ions randomly occupy the  $16d$  position in the Ni/Mn disordered  $Fd\bar{3}m$  structure. The delithiation of the  $P4_332$  spinel basically proceeds in separate two-phase reactions between  $\text{LiNi}_{0.5}\text{Mn}_{1.5}\text{O}_4$  ( $\text{Li}_{1.0}$  phase) and  $\text{Li}_{0.5}\text{Ni}_{0.5}\text{Mn}_{1.5}\text{O}_4$  ( $\text{Li}_{0.5}$ ) at  $\sim 4.70$  V, and between  $\text{Li}_{0.5}\text{Ni}_{0.5}\text{Mn}_{1.5}\text{O}_4$  and  $\text{Ni}_{0.5}\text{Mn}_{1.5}\text{O}_4$  ( $\text{Li}_{0.0}$ ) at  $\sim 4.74$  V. On the other hand, the  $Fd\bar{3}m$  spinel shows a single-phase reaction (solid solution behavior) on going from the  $\text{Li}_{1.0}$  phase to  $\text{Li}_{0.5}$  phase [1].

Solid-state nuclear magnetic resonance (NMR) spectroscopy is a useful technique for investigating the chemical environments on a specific element in the battery materials. In particular, the  $^{6,7}\text{Li}$  NMR has been widely applied for the chemical structure characterization of the pristine and delithiated positive electrode materials, because it gives direct information about mobile Li ions. Previous studies reported the difference in Li local environments between the ordered and disordered  $\text{LiNi}_{0.5}\text{Mn}_{1.5}\text{O}_4$  [2]. We here examine the delithiation and lithiation behavior of ordered and disordered  $\text{LiNi}_{0.5}\text{Mn}_{1.5}\text{O}_4$  by using *in situ* (*in operando*)  $^7\text{Li}$  NMR and *ex situ*  $^6\text{Li}$  MAS NMR spectroscopy. The *in situ*  $^7\text{Li}$  monitoring of the ordered spinel revealed a clear appearance and subsequent disappearance of a new signal from  $\text{Li}_{0.5}\text{Ni}_{0.5}\text{Mn}_{1.5}\text{O}_4$ , suggesting the two-phase reaction processes among  $\text{Li}_{1.0}$ ,  $\text{Li}_{0.5}$ , and  $\text{Li}_{0.0}$  phases in agreement with the *in situ* XRD studies (See figure). High-resolution  $^6\text{Li}$  MAS NMR spectra, which give information about the Li environment in details for the disassembled samples, suggested that the nominal Li-free phase  $\text{Li}_{0.0}\text{Ni}_{0.5}\text{Mn}_{1.5}\text{O}_4$  can accommodate a small amount of Li ions in its structure. The tetragonal phase  $\text{Li}_{2.0}\text{Ni}_{0.5}\text{Mn}_{1.5}\text{O}_4$ , which was formed when the cell was discharged down to 2.0 V, was very different in Li environment between the ordered and disordered spinels. It is found that  $^{6,7}\text{Li}$  NMR is highly sensitive not only to the Ni/Mn ordering in  $\text{Li}_x\text{Ni}_{0.5}\text{Mn}_{1.5}\text{O}_4$  but also to the delithiation/lithiation process during charge-discharge cycle.

Copper-tin alloy is a useful material for corrosion resistance and soldering<sup>1</sup>. Electrodeposition is a relatively inexpensive technique is not practical for the production of CuSn alloy in the aqueous solution because the electrode potentials for Cu and Sn depositions are far apart.

Room-temperature ionic liquids (RTILs) composed of organic cations and various anions are liquid salts staying as a liquid phase even at room temperature. Most RTILs have unique properties such as nonflammability, negligible vapor pressure, high conductivity, wide electrochemical window. We have succeeded in electrodeposition of various pure metals and alloys, which cannot be produced in aqueous solutions, in the RTILs. Recently we found that Cu-Sn alloy tubes can electrochemically be obtained in the 1-ethyl-3-methylimidazolium dicyanamide (EMI-DCA) containing Cu(I) and Sn(II) without any templates<sup>2</sup>. In this paper, we report the template-free electrodeposition of Cu-Sn alloy tube and in-situ SEM observation of the alloy electrodeposition process.

The electrolytes were prepared by dissolution of proper amounts of anhydrous CuCl and SnCl<sub>2</sub> into the EMI-DCA. All electrochemical experiments were carried out in a three-electrode cell. Cu spiral wire was used as a counter electrode and a Pt wire immersed in a melt solution containing ferrocene/ferrocenium (50/50mol%) in a fritted glass tube was used as a reference electrode. Ni foils were used as the substrate for electrodeposition. For in-situ SEM observation study a specially-manufactured sandwich cell was used. A 100 mesh Ni sheet as used as a working electrode for metal deposition; Cu foil and wire were used as counter and reference electrodes, respectively. The glass fiber membrane was used as the separator between each electrode.

The electrochemical behavior of the individual copper<sup>3</sup> and tin<sup>4</sup> in EMI-DCA has been studied previously. Based on these reports, electrodeposition of Cu-Sn alloys was conducted under different conditions. Figure 1 shows hollow tubes<sup>2</sup> obtained at a low current density of  $-0.4 \text{ mA cm}^{-2}$  from EMI-DCA containing (A) 33mM Cu(I)- 16.5mM Sn(II) at 40°C. According to the XRD results, while Cu<sub>10</sub>Sn<sub>3</sub> hollow tubes could be obtained from Cu(I)-rich solution. Although we proposed a plausible formation mechanism for the alloy deposits in our previous paper<sup>2,5</sup>, still it is not clear. Here, we attempted to visually investigate the growth mechanism by using an in-situ scanning electron microscope (SEM) observation method established in our laboratory. A part of the deposition process was successfully observed in real time shown in Figure 2.

# Single ion activity, pH, liquid junction potential, and the essence of electrochemistry: in response to “A pH centenary” by Robert de Levie

Takashi Kakiuchi<sup>1,2</sup>, Masahiro Yamamoto<sup>1</sup>

1. CREST-JST, Department of Chemistry of Functional Molecules, Konan University, 8-9-1 Okamoto, Kobe 658-8501, Japan
2. pH Science and Technology Laboratory, Kinomoto 1058, Wakayama 640-8453, Japan  
kakiuchi.takashi.55e@st.kyoto-u.ac.jp

An article published last year, “A pH centenary,” by Robert de Levie [1] is not simply a scholarly and elaborative essay on history of pH, but is a provocative proposition of his opinion that pH or the scale of acidity of an electrolyte solution should be based on the concentration, rather than the single ion activity, of hydrogen ion. His reasoning is “the activity (or, more precisely, the corresponding activity coefficient) of a single ionic species is a supposedly thermodynamic concept, introduced by G. N. Lewis. However, it cannot be defined thermodynamically, and therefore does not have a physical existence and cannot be measured” [2].

The thermodynamically immeasurable nature of the single ion activity has been the subject of discussion over nearly one hundred years [3] and supposed to be well understood. However, that some discussions on this issue, including the de Levie’s essay [1], among electrochemists have continued to date suggests that a certain important point has been overlooked in those preceding discussions and polemics. In fact, both sides, de Levie and Bates [4] (or IUPAC2002 recommendations [5]) seem to have a common understanding that the cell voltage of the cell,  $\text{Pt}|\text{H}_2(\text{g}), \text{aq. HCl}||\text{AgCl}|\text{Ag}$ , i.e., the so-called “Harned cell”, provides the thermodynamically defined mean activity coefficient of HCl. This background unfortunately seems to make their arguments unnecessarily involved and complicated.

A hidden nonthermodynamic assumption in use of the “Harned cell” is the negligible diffusion potential existing, however small, across the liquid junction that must be present somewhere within the cell [6], which in fact is inevitable in any electrochemical cells by nature. As is well known or too obvious, any galvanic cell consists of two redox couples that are placed separately in the cell to minimize direct redox reactions between them, and, hence is intrinsically nonthermodynamic [7]. In this respect, an approach, “thermodynamic properties...by means of cells without liquid junctions” [8] promoted by R. S. Harned might have dazzled many textbooks of electrochemistry, despite the warning by MacInnes[6], by depicting the cell as if thermodynamic properties are obtainable through “equilibrium cell voltage.” If we start with the premise that a liquid junction is an important player in any electrochemical cell but the liquid junction potential may be made negligibly small by use of a salt bridge or otherwise, we will be able to obtain a good estimate of the magnitude of hydrogen ion activity, undoubtedly a non-thermodynamic quantity, with the extent of the uncertainty determined by the residual liquid junction potential. Unfortunately, the performance of a salt bridge of a concentrated aqueous KCl solution or similar ones, which have been used over more than a hundred years, is not necessarily satisfactory. However, a new salt bridge that consists of a moderately hydrophobic ionic liquid (ILSB) [9-11] has been shown to reduce the liquid junction potential between aqueous HCl solutions of different concentrations to as low as 0.5 mV[12], which demonstrates that it is possible by use of an ILSB to narrow down the pH based on hydrogen ion activity within  $\pm 0.01$ . By simply using a better salt bridge, it is thus possible to have a good estimate of “thermodynamically immeasurable” single ion activity of hydrogen and other ions. Starting with an intrinsically nonthermodynamic electrochemical cell and a nonthermodynamic assumption which is inevitably required for any type of electrochemical cell, we may obtain non-thermodynamic quantities that can be useful for better understanding of the relevant thermodynamic properties. My (T.K.’s) essay on de Levie’s view on measurability of single ion activity written before publication of [1] is available [13]; a full version in response to [1] is in preparation.

Submit to the Symposium 18: General session

Three kinds of wire beam electrodes(WBE) composed by zinc and mild steel wires were developed, which was used to simulate hot-dip galvanized steel with spot coating defect in different dimension, to obtain the spatial distributions of potential and current density and their variations with time during the galvanic corrosion. The electrochemical characteristics among these WBEs were also investigated. The results showed that zinc wires within the WBEs could provide enough cathodic protection to steel wires after immersed in seawater, with surface area ratio of zinc wires versus steel wires as 1:120, 9:112, and 25:76, respectively. The potential and current density distributions were found to be inhomogeneous among zinc wires; firstly, main anodic areas shifted randomly among the zinc wires adjacent to steel wires, then transferred to the direction away from steel wires, and finally occurred on the zinc wires farther. The similar heterogeneous phenomenon also appeared on steel wires surface on which hydrogen evolution might take part in the cathodic process occurred. The current density of water molecule reduction reaction, along with dissolved oxygen reduction reaction, decreased with the ratio of the surface area of steel wires versus zinc wires rising.

Fig.1 Spatial open circuit potential distribution of zinc/steel-WBE after immersed in seawater for 0.5 h:

(a) WBE-1×1S; (b) WBE-3×3S; (c) WBE-5×5S

# Dynamics of Interfacial Oxide Formation during Anodization of Valve Metal Superimposed Ultra-Thin Films

Andrei Ionut Mardare<sup>1</sup>, Christian M. Siket<sup>2</sup>, Cezarina Cela Mardare<sup>1</sup>, Siegfried Bauer<sup>2</sup>,  
Achim Walter Hassel<sup>1</sup>

<sup>1</sup> Christian Doppler Laboratory for Combinatorial Oxide Chemistry at the Institute for Chemical  
Technology of Inorganic Materials, Johannes Kepler University Linz, 4040 Linz, Austria

<sup>2</sup> Soft Matter Physics, Johannes Kepler University Linz, 4040 Linz, Austria  
andrei.mardare@jku.at

Anodization of superimposed valve metals has been in the focus of the electrochemical community due to the necessity of better understanding the anodic oxide formation in such cases with direct applications in capacitors, high-k materials and MOS-based devices or sensors. In particular, superimposed layers containing Al are highly relevant due to its abundance, high band-gap and already implemented industrial processing. Both early theoretical and experimental studies revealed that if the underlying metal forms a lower ionic resistivity oxide as compared to the outer  $\text{Al}_2\text{O}_3$ , "fingers" of the inner metal oxide may penetrate into the outer oxide layer [1-3]. The anodic oxide mixing during the anodization is based on an inherent competition for oxygen between different valve metal ions regulated by their individual ionic transport numbers [4, 5]. However, even though a principally correct theoretical prediction describing the formation of a layered anodic oxide when the underlying film has a high ionic resistivity (e.g. Al) was formulated [1], studies on the metals interfacial anodization are scarce in spite of their tremendous importance for the overall anodic oxide properties. Moreover, the oxide-oxide interface remains unexplored. Hafnium is an excellent candidate for such studies due to its extremely low ionic transport number combined with its amorphous nature when deposited at room temperature [6].

In the present work, the anodization behavior of Hf and Al stacked thin films, sequentially deposited from vapor phase without breaking vacuum, was investigated using scanning droplet cell microscopy. The effect of the ultra-thin nature of the superimposed film on the final oxide properties was studied. Surface microstructure and crystallographic analysis revealed the formation of highly textured and compact films for Hf thicknesses above 7.5 nm. Cyclic voltammetry suggested the formation of discrete anodic layers when Hf was superimposed on Al starting with pure  $\text{HfO}_2$  on the surface, a mixture of  $\text{HfO}_2$  and  $\text{Al}_2\text{O}_3$  as an intermediate layer and pure  $\text{Al}_2\text{O}_3$  in depth of the films. The finding of a mixed interfacial oxide layer completes the initial Pringle's theory which predicted a full oxide segregation [1]. Coulometric investigations revealed oxide formation factors of  $2.2 \text{ nm V}^{-1}$  for  $\text{HfO}_2$  while for pure  $\text{Al}_2\text{O}_3$  a maximum of  $1.4 \text{ nm V}^{-1}$  was measured. Electrochemical impedance spectroscopy performed for various Hf thicknesses and different final anodization potentials revealed almost ideal dielectrics formed from mixed  $\text{HfO}_2/\text{Al}_2\text{O}_3$ , permittivities up to 26 being measured for the anodized Hf/Al films. Surface analytical investigations and depth profiling confirmed the discrete anodic layer growth together with the mixing of both anodic oxides (see Figure).

Ionic liquids (ILs) are essentially pure electrolytes, being composed of unsolvated cations and anions. As such they can behave as excellent electrolytes, both dissolving compounds and facilitating electron transfer. This talk will describe a new family of ionic liquids which are themselves formed by reversible electron transfer; referred to as redox ionic liquids (RILs). In particular, this talk will focus upon ferrocene/iodine-based ionic liquids (Figure 1), and will give an overview of their physiochemical electrochemical and properties.

Figure 1. Ferrocene + iodine

Ferrocenium triiodide ionic liquid

As equilibrium ionic liquids, the position of the (electron transfer) equilibrium is temperature and potential dependent, making them both distillable and electrochemically switchable electrolytes. As 100% of the liquid is redox active they represent potential ‘high power density’ electrolytes for electrochemical processes such as supercapacitor and redox flow batteries. This talk will focus upon the application of their temperature-sensitive redox equilibrium for excellent waste heat harvesting in thermoelectrochemical cells, via which a temperature difference can be directly converted into an electric current (Figure 2(a)).

The ionicity of the RILs was found to depend upon the relative redox potentials of the component parts and the stoichiometry of their composition. Such RILs are either inherently “super” ionic electrolytes, or are easily made “super” ionic by altering the stoichiometry (Figure 2(b)). This stems from polyiodide chains (Grotthuss mechanism) and potentially ferrocene-ferrocenium electron propagation.

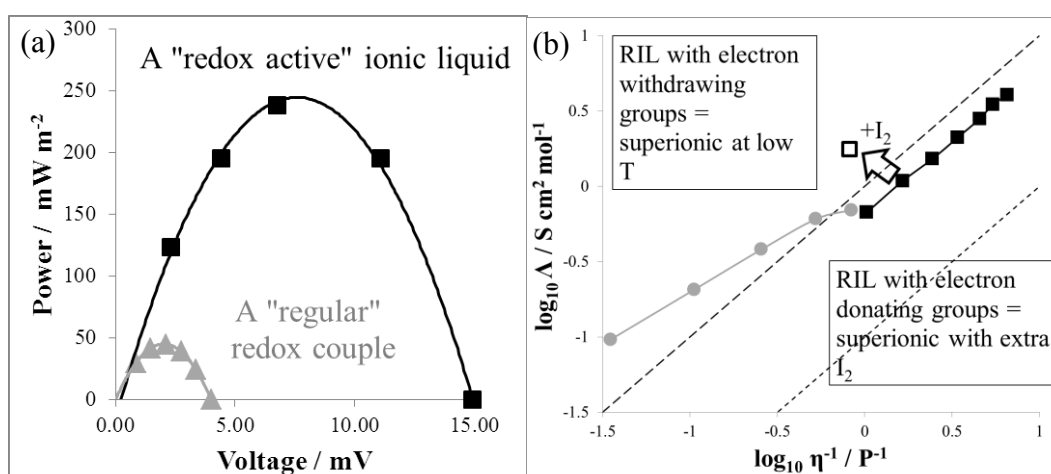

Figure 2(a) Superior power harvesting of an RIL using a simple battery casing as a thermoelectrochemical cell (temperature difference of 30 K), and (b) Walden plot displaying the “good” ionicity of [DiButylFc][I<sub>3</sub>] (■), the “super” ionicity of [DiBuFc][I<sub>3</sub>] (□) and temperature-dependent ionicity of [DiButyryl][I<sub>3</sub>] (●).

# Thermal membrane potential – Application to thermoelectric power generation

Thermoelectric materials offer a means for converting thermal energy directly into electricity, with a plethora of possible applications [1]. However, poor efficiency and high price of the materials are still hindering the commercialization of thermoelectric semiconductors, which has generated interest in other forms of thermoelectricity [2,3]. Ion-exchange membranes have been suggested as an alternative to semiconductors in terms of thermoelectricity [3], as they can provide larger voltage per temperature difference [4,5], lower fabrication costs and low thermal conductivity [3]. However, to the best of our knowledge, no measurements on the thermoelectric power production with thermogalvanic cells and ion-exchange membranes have been made.

In this work we evaluate the thermal membrane potential in various 1-1 electrolytes and apply the thermally generated potential difference to electric power generation. The left panel of Figure 1 shows a sketch of the measurement cell of uniform electrolyte concentration, with one hot stream flanked by commercial anion and cation-exchange membranes. The temperature difference creates an electric potential difference, with the positive electrode adjacent to the hot stream. Connecting the cell to a load allows the transport of ions through the membranes, which in turn drives electrochemical reactions at the electrodes (e.g. Ag/AgCl).

We evaluate theoretically the thermal membrane potential taking into account the concentration dependence of the ionic heats of transport, the thermal polarization [6] and the concentration polarization caused by the Soret effect [7] in the boundary layers adjacent to the membrane surfaces. The theoretical predictions are compared to the measured values for different electrolytes and concentrations. We also show that it is possible generate electric power with the proposed cell, and measure how the power output behaves as a function of temperature difference (Figure 1, right panel) and concentration. The theory shows good agreement with the experimental results for both thermal membrane potential and power in various electrolytes and concentrations, and enables comparison and prediction of the potential with different membranes and electrolytes in different cell designs. Although still at the proof-of-concept level, the maximum power is already similar to that of other emerging thermoelectric materials [2].

**Fig 1.** Left: Sketch of the measurement cell with anion-exchange (A) and cation-exchange membranes (C). Electrode reactions are driven by the thermal electrodiffusion of ions; the positive electrode is the one closer to the hot stream. Right: Thermally generated voltage  $\Delta\phi$  and power output vs. current density measured for 0.1 mol/L NaCl with different temperature differences: 5.4 K (blue), 9.3 K, 13.3 K, 16.5 K, and 20.5 K (red).

This study reports a novel enzyme-free, label-free amperometric method for direct detection of hemoglobin A1c (Hb<sub>A1c</sub>), a potent biomarker for diabetes diagnosis and prognosis. The method relies on an electrode modified with poly(3-aminophenylboronic acid) (PAPBA) nanoparticles (20-50 nm) and a sensing scheme named “binding-induced ion flux blocking.” The PAPBA nanoparticles were characterized by FT-IR, XPS, TEM, and SEM. Being a polyaniline derivative, PAPBA showed an ion-dependent redox behavior, in which insertion or extraction of ions into or out of PAPBA occurred for charge balance during the electron transfer process. The polymer allowed Hb<sub>A1c</sub> selectively bound to its surface via forming the *cis-diol* linkage between the boronic acid and sugar moieties. Voltammetric analyses showed that Hb<sub>A1c</sub> binding decreased the redox current of PAPBA; however, the binding did not alter the redox potentials and the apparent diffusivities of ions. This suggests that the redox current of PAPBA decreased due to an Hb<sub>A1c</sub> binding-induced ion flux blocking mechanism, which was then verified and characterized through an *in situ* electrochemical quartz crystal microbalance (EQCM) study. Assay with Hb<sub>A1c</sub> by differential pulse voltammetry (DPV) indicates that the peak current of a PAPBA electrode has a linear dependence on the logarithm of Hb<sub>A1c</sub> concentration ranging from 0.975 to 156  $\mu$ M. The Hb<sub>A1c</sub> assay also showed high selectivity against ascorbic acid, dopamine, uric acid, glucose and bovine serum albumin. This study has demonstrated a new method for developing an electrochemical Hb<sub>A1c</sub> biosensor and can be extended to other label-free, indicator-free protein biosensors based on a similar redox polymer electrode.

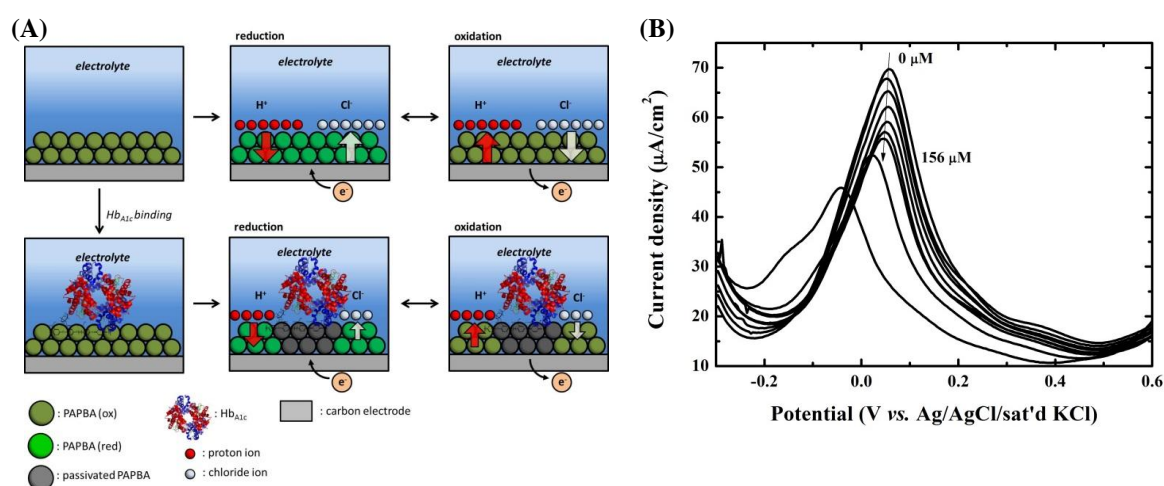

Figure 1 (A) The proposed mechanism of the ion fluxes change of PAPBA nanoparticles with Hb<sub>A1c</sub> binding. (B) DPVs of the PAPBA/SPCE reacted with Hb<sub>A1c</sub> samples with different concentrations.

# Functionalization of Conductive Carbon Supports at Water/Oil Interfaces with Non-Precious Metal Hydrogen Evolution Catalysts

Micheál D. Scanlon,\* Andrés Molina Osorio

University College Cork

Department of Chemistry & Tyndall National Institute, University College Cork, Cork, Ireland

\*micheal.scanlon@ucc.ie

Generation of molecular hydrogen ( $H_2$ ) by the electrochemical reduction of water is key to developing several clean-energy technologies (e.g.,  $H_2$  fuel cells). While noble metals, such as Pt, effectively facilitate the electrochemical  $H_2$  evolution reaction (HER), cheaper, earth-abundant, non-precious metal containing  $H_2$  evolution catalysts (HECs) are required to make the clean-energy technologies economically viable. In this regard, significant research has been devoted to their development and lead candidates include transition metal dichalcogenides ( $MoS_2$ ), carbides ( $Mo_2C$ ), borides ( $MoB$ ) and metal phosphides ( $Ni_2P$ ).<sup>(1)</sup> Furthermore, a HECs activity can be markedly improved by nanoscale deposition onto conductive materials (such as graphene). The latter both increases the HECs surface-to-volume ratio, exposing more active sites, and improves electron transport between the reducing agent and catalyst (the conductive support acts as an “electron superhighway”).<sup>(2)</sup>

**Fig. 1:** Cyclic voltammetry of the ion transfer (IT) responses for a biphasic system containing  $[MoS_4]^{2-}$  in the aqueous phase both in the absence and presence of an oxidizing agent (TCNQ) in the organic phase. Additional IT responses with TCNQ indicate a biphasic reaction has taken place.

The interface between two immiscible electrolyte solutions (or ITIES) offers a unique platform at which to deposit nanoscale HECs onto conductive materials free-floating at the water/oil interface. These experiments are performed under ambient conditions and without the use of traditional solid-electrodes, allowing ease of recovery of the resultant advanced functionalized materials. Initial studies in this field involved the *in situ* deposition of Pt and Pd nanoparticles at the water/oil interface by reducing an aqueous metallic salt (e.g.,  $[PdCl_4]^{2-}$ ) using a lipophilic electron donor (decamethylferrocene; DMFc) via interfacial electron transfer (IET).<sup>(3)</sup> Depending on the reduction potentials of the species in the respective phases, IET can occur spontaneously or be controlled electrochemically by varying the interfacial Galvani potential difference ( $\Delta_o^w\phi$ ).

Recently, Dryfe’s group introduced an elegant approach to functionalize graphene at the water/oil interface by transferring graphene, grown on a polymer by CVD, onto the interface. In this instance, metallic (Pd and Au) nanoparticle deposition occurred preferentially on the graphene rather than at the bare interface with IET occurring via the conductive graphene.<sup>(4)</sup>

Herein, we investigated the biphasic deposition of transition metal dichalcogenide nanoparticles onto graphite and CNTs adsorbed at the water/oil interface from aqueous  $[MoS_4]^{2-}$ . Both the oxidative (Equation 1 and Figure 1) and reductive (Equation 2) pathways were considered, using lipophilic electron acceptors (tetracyanoquinodimethane; TCNQ) and donors (DMFc), respectively.

The catalytic activity of the resulting  $MoS_x$ /graphite and  $MoS_x$ /CNT materials towards the HER were characterized by linear polarization curves and electrochemical impedance spectroscopy.

The semiconductor-mediated photochemical reactions are an attractive tool for the degradation of pollutants as the excitation of electronic molecular states at energies corresponding to the ultraviolet light may induce easier chemical bond breaking. However, the low photonic efficiency of most semiconductors is still a challenge that calls out for a research to be conducted to optimize the optical features of semiconductor materials, or to explore the use of novel materials in this kind of applications. [1] The incorporation of carbon materials as additives to semiconductor has long proved to be an interesting strategy to improve the performance of such carbon/semiconductor composites in several fields. However, despite the superior performance of the hybrid photocatalysts, the exact role of the carbon phase remains rather unclear. [2,3]

To throw some light on the mechanisms of the photoinduced processes occurring in such hybrid carbon/semiconductor catalysts, we have investigated the photoelectrochemical response of thin film electrodes under different conditions of illumination (UV-vis light source and monochromatic light). Several nanoporous carbon materials and inorganic semiconductors (TiO<sub>2</sub>, WO<sub>3</sub>, Bi<sub>2</sub>WO<sub>6</sub>) have been examined for the preparation of the hybrid photocatalysts.

As a first step, spectroscopic techniques have been applied to investigate the structural and optical properties of the carbon/semiconductor composites compared to the intrinsic characteristics of the unsupported semiconductor. The second approach consisted in the preparation of thin film electrodes to explore the photoinduced reactions at the interface under illumination and bias potential.

Our results point out that beyond the beneficial effect of the porosity, the carbon matrix does play an important role in the photo-induced reactions, hence different mechanisms have been postulated and will be discussed considering the characteristics of the carbon material. Moreover, our data showed a strong dependence of the photoelectrochemical response of the hybrid catalysts with the origin and structure of the carbon phase, the composition of the inorganic semiconductor and the irradiation source.

<sup>1</sup>*Instituto Nacional del Carbón (INCAR, CSIC), 33011 Oviedo, Spain,* <sup>2</sup>*Dept. Química Física e Instituto de Electroquímica, Universidad de Alicante, E-03080 Alicante, Spain.*

\*conchi.ania@incarcsic.es

The diversity of carbon materials used as electrodes in electrochemical applications stands from the varied bulk and surface properties (such as the structural polymorphism, chemical stability, rich surface chemistry and electronic conductivity) among the members of the carbon family, which depend on the spatial arrangement of the carbon atoms [1]. Besides carbon allotropes (graphite, graphene, carbon nanotubes), the use of nanoporous carbon materials having large surface areas (ranging between 500-2500 m<sup>2</sup>/g) as electrodes, has opened up new opportunities in electrochemistry [2].

Although most of them have limited electronic conductivity derived from a poor structural order [3], the main advantage of nanoporous carbon electrodes in electrochemical application relies on the increased adsorption and diffusion derived from the surface area (provided the adequate distribution of pore sizes); such properties may bring about an enhancement in the sensitivity of an electrochemical sensor, or favour direct electron transfer reactions at the electrode surface. However, to effectively take advantage of the textural features of carbon electrodes leading to an enhanced contact between the electrode surface and the target molecule, the internal structure (porosity) of the carbon must be accessible.

In this work we have explored the electrochemical features of highly mesoporous carbon electrodes prepared from sol-gel polycondensation reactions and nanocasting procedures [4,5] as porous substrates for the immobilization of cytochrome c (Cyt-c) and glucose oxidase (GOx). Immobilization of Cyt-c and GOx was optimized according to protein concentration, buffer ionic strength solution, temperature, adsorption time and nature of nanoporous carbons. The pseudo peroxidase activity of Cyt-c and the response of GOx to the detection of glucose.

Our results showed that the nanoconfinement in the porosity of the carbon increased the electron transfer rate and electrical contact. This demonstrates the critical role of matching the molecular dimensions of the target molecule with the mean pore size of the carbon electrode for an optimal and efficient molecular orientation minimizing the random distribution at non-efficient positions. Additionally, surface functionalization of the nanoporous carbon electrode is also important as it may control the conductivity, wettability and hydrophobicity, creating favorable/unfavorable interactions with the immobilized molecule that end up controlling the electrochemical response.

In this communication, observation of a 2D self-propagation catalytic reaction on surfaces is described. Huisgen 1,3-dipolar cycloaddition, known as click chemistry<sup>1</sup>, is one of the most used catalytic reaction nowadays as it is a highly versatile and fast coupling reaction. It can be used as well with biological samples in water or in classic organic synthesis. In parallel, interest in chemically modified surfaces has been growing for several decades due to their many applications in various scientific areas. Among many methods to chemically modified surfaces, click chemistry coupling is also often used for its efficiency and its great selectivity. This coupling reaction between an azido and a free alkyne is catalyzed by Cu(I) which can be generated chemically or electrochemically, leading to “electro-click chemistry reaction” in the latter case. Recently, using Scanning Electrochemical Microscopy (SECM), localized electro-click chemistry reactions were successfully performed.<sup>2</sup> “Self-induced” electro-click chemistry reaction can be achieved when using a molecule that is at the same time a reactant and the catalyst.<sup>3</sup> In this communication, we will specifically study local self-induced electro-click chemistry reaction onto self-assembled monolayers by SECM. It will be demonstrated that using this specific class of molecule (see scheme), catalytic properties can be transferred to the surface and that 2D self-propagation of the catalytic reaction on the surface can be seen. Particular attention will be paid to the determination of the experimental conditions needed to perform and monitor these experiments in unbiased conditions (the substrate is not electrically connected).<sup>4</sup>

# New Strategies to Manufacture Low-cost Thin-film MicroElectrode Arrays for Electroanalysis

Ana Fernández-la-Villa\*, Diego F. Pozo-Ayuso, Mario Castaño-Álvarez  
MicruX Technologies. Severo Ochoa Bldg. Julián Clavería s/n, Floor -1, Room 4 & 6, 33006 Oviedo  
(Asturias) SPAIN.

\*[anafv@micruxfluidic.com](mailto:anafv@micruxfluidic.com)

Electroanalysis is a very important analytical field that has demonstrated its potential for solving real-life analytical problems by understanding of the fundamentals of electrode reactions and the principles of electrochemical methods. The high performance, small size, low power requirements and low cost of electrochemical sensors has led to many important detection systems.

In this sense, thin-film microtechnologies enable the fabrication of metal-based electrodes with high precision and resolution in a cost-effective way. Besides, these technologies allow the fabrication of microelectrodes which show at least one dimension not greater than 25  $\mu\text{m}$ . Microelectrodes provide unique electrochemical properties such as small capacitive-charging currents, reduced ohmic ( $iR$ ) drop, and steady-state diffusion currents. Moreover, the small size of the microelectrodes enables measurements on very limited solution volumes.

Thus, microelectrodes are currently available on different materials, geometric shapes and configurations. In this work, new **microelectrode arrays** (MEA) based on pinholes with a honeycomb microstructure have been designed and manufactured on a metal working single-electrode. Microelectrode arrays overcome the extremely large current densities yet very small absolute currents of a single microelectrode and have both helpfully high current densities and satisfactory output signals. The basic layout of two microelectrode arrays is shown in **Figure 1**.

**Figure 1.** Basic layout of the microelectrode arrays and typical cyclic voltammograms for redox compounds

The new electrochemical sensors are based on a three-electrode (working – WE, reference – RE and auxiliary – AE) approach. The metal structure of electrodes is fabricated by a photolithographic process. A SU-8 resin layer is used to delimit the electrochemical cell as well as define the microstructure of the array. Thus, the working electrode (1 mm diameter) consists of a metal surface (platinum or gold) coated with the SU-8 layer (3–4  $\mu\text{m}$  thickness) in which is defined different pinholes with a honeycomb microarray structure, all in the same photolithographic process. Two different microstructures were achieved, one based on ninety 10- $\mu\text{m}$  diameter pinholes with 100- $\mu\text{m}$  pitch each other and another based on five hundred 5- $\mu\text{m}$  diameter pinholes with 50- $\mu\text{m}$  pitch each other. In **Figure 1** is shown the typical microelectrode behavior for both structures reaching the steady-state in a short time.

Microelectrodes offer a very suitable analytical tool in applications such as the study of electrochemical reaction mechanisms and kinetics, trace electrochemical analysis, electrochemical reactions in solutions of very high resistance, in-vivo measurements on biological objects, multichannel (bio)sensors as well as detection in flowing liquids (FIA, HPLC, CE...).

# Validating a Central Approximation in Theories of Regular and Random Electrochemical Electrode Arrays

O. Sliusarenko, A. Oleinick, I. Svir, C. Amatore  
CNRS UMR 8640 PASTEUR, Ecole Normale Supérieure-PSL Research University,  
Département de Chimie, Sorbonne Universités, UPMC Paris 6  
24, rue Lhomond, 75005 Paris, France  
*christian.amatore@ens.fr; irina.svir@ens.fr*

Regular electrode arrays generally possess a symmetry which (under certain conditions) allows to reduce their mathematical description to consideration of a single electrode of this array within the laterally bounded domain (known as ‘unit cell’ or ‘diffusion domain’) [1, 2]. In this case by multiplying the simulated current of the single cell by the number of electrodes in the array one would obtain an electrochemical response of the whole array. The electrodes in arrays are generally ordered in a hexagonal or square patterns, which result in hexagonal or square cross-sections of the unit cells, respectively. A straightforward approach to the mass-transport problem in such cells would require complex and time-consuming 3D simulations. Therefore almost always an approximation is made in simulations by replacing the original cross-section with the circular one of the same surface area. At one hand, this greatly facilitates the simulations due to the possibility to formulate the mass-transport problem in two dimensions (2D). On the other hand, although this approach was proven to be effective in practice, the error introduced by this approximation, to the best of our knowledge, was never been studied or even estimated.

The error associated with the approximation is based on the fact that it is impossible to pave the plane with non-intersecting circles contrary to the perfect plane paving with hexagons or squares as well as due to the different possible diffusion pathways within the single cells with different cross-sections. In order to assess quantitatively this approximation we performed 3D Brownian motion simulations for the single cells of square, hexagon and circular cross-sections equipped with disk electrode. Moreover the situations with inlaid, recessed and protruding electrodes were also considered for each cross-section shape. Notwithstanding the completely different diffusion patterns observed in these systems, the obtained results showed that the approximation gives rise to an experimentally indistinguishable error (less than 5%) for all considered systems [2]. The only exception (i.e. when the error is larger than 5%) was the case when the electrode radius was extremely close to the characteristic size of the cross-section, i.e. the situation when the neighbouring electrodes in the array almost touch each other. The latter situation is of low experimental interest and in addition such systems exhibit the same behavior as a planar electrode with the surface area of the whole array (except of the initial times of the experiment).

With the same idea in mind, to check the validity of the circular diffusion domain approximation, the random arrays were considered. We dealt with 2D Gaussian (i.e. centered) and space uniform distributions of the electrodes in array. The electrochemical response of the array can be obtained by the following procedure: (i) construct the diffusion domains of each electrode (via Voronoi tessellation); (ii) build up the histogram of diffusion domains surface areas; (iii) using circular approximation of the diffusion domain simulate the current with for each bin (i.e. different values of the single cell surface area) in the histogram; (iv) sum up the responses for each bin with an appropriate weight taken from the histogram. This approach was compared with similar approach where distribution of the domain surfaces areas was described analytically (i.e. fit of the histogram) and heuristic analytical expressions were used for a domain with a given surface area. The reference for these two approaches was a simulation of the whole randomly generated array. The outcome of these simulations reveal that any of the weighting procedures works perfectly for initial and intermediate times of the experiment, however, may lead to a discrepancies of about 5-10% at larger times. The latter occurs due to the presence of the domains with very large surface area as well as compelled asymmetry of such domains [3].

# Thin Layer Ionophore-Based Membranes Electrochemically modulated by Poly(3-octylthiophene) for Multianalyte Detection

Maria Cuartero, Gaston Crespo and Eric Bakker

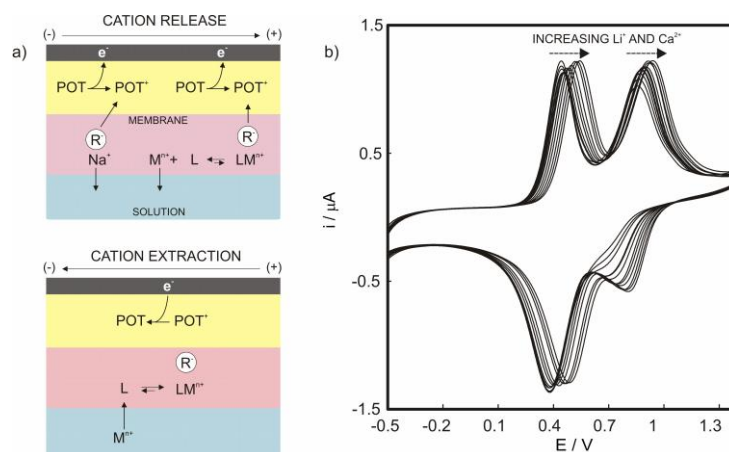

Department of Inorganic and Analytical Chemistry, University of Geneva, Quai Ernest-Ansermet 30, CH-1211 Geneva, Switzerland.

Email address: Maria.Cuartero@unige.ch

We report here on the selective voltammetric transfer of lithium and calcium into an ionophore-based polymeric thin layer membrane back side contacted with electropolymerized poly(3-octylthiophene) (POT), an anion exchanger conducting polymer. It has been demonstrated that POT permits to modulate the ion-transfer process across the membrane/sample interface by its oxidation.<sup>1,2</sup> The additional incorporation of either calcium or lithium ionophore into the thin membrane permits the discrimination between background electrolyte (10 mM NaCl) and primary analytes (Figure 1a). The peak displayed in the cyclic voltammogram is gradually displaced to positive values with increasing activity of the corresponding cation, which follows precisely the Nernst equation. In contrast to other techniques, for instance rotating electrode stripping voltammetry, these electrodes exhibit a linear range suitable for biomedical and environmental applications ( $10^{-5}$ - $10^{-2}$  M).

An interesting selectivity characteristic is observed when both ionophores are incorporated simultaneously in the same membrane. Applying a linear sweep potential, each cation shows its own peak in a distinct potential range (Figure 1b). These peaks follow a Nernst shift with increasing concentrations of lithium and calcium. With this new approach both cations can be easily determined in the presence of 10 mM NaCl. To the best of our knowledge, this is the first time such selective multianalyte analysis is demonstrated with an ion transfer electrochemical technique.

Current efforts in our laboratory to further improve this approach include the use of thin layer samples to develop exhaustive processes and extending the detection to other systems such as polyion sensors.

**Figure1.** a) Scheme of the electrochemical process ( $R^-$ =cation exchanger,  $M^{n+}$ = $Li^+$  and/or  $Ca^{2+}$ ,  $L$ =ionophore). b) Cyclic voltammograms obtained for increasing equimolar concentrations of lithium and calcium. (Scan rate of  $100\text{ mVs}^{-1}$ ).

# Surface-Initiated Enzymatic Polymerization Based Signal Amplification Strategies for Sensitivity Improvement of Electrochemical DNA Sensors

Ying Wan, Pengjuan Wang, Yan Su\*

School of Mechanical Engineering, Nanjing University of Science and Technology  
Xiaolingwei Street 200, Nanjing, Jiangsu, 210094, China  
wanying@njust.edu.cn

Electrochemical DNA (E-DNA) sensors have great potential in point-of-care diagnosis because of their ability to produce a simple, accurate and inexpensive platform for DNA sensing. However, it is difficult to detect extremely low abundance of DNA biomarkers in clinical samples. Thus different signal amplification methods have been developed to improve the sensitivity of E-DNA sensors. We have developed a serial of signal amplifying E-DNA sensors based on terminal deoxynucleotidyl transferase (TdT) mediated surface-initiated enzymatic polymerization (SIEP). The first one was simply constructed by a capture probe to recognize target and the TdT catalyzed elongation of target DNA. We developed an ultrasensitive E-DNA sensor based on the signal amplification efficiency of nanoprobe and surface-initiated enzymatic polymerization (SIEP). In this method, a sandwich-type hybridization structure was formed by capture probe, target and signal probe. Capture probe was immobilized onto gold electrode and signal probe was immobilized onto gold nanoparticles (AuNPs). Upon hybridization, AuNPs modified with signal probe DNA were bound to the electrode and then subjected to terminal deoxynucleotidyl transferase (TdT)-mediated SIEP. During the extension reaction, biotin labels are incorporated into the SIEP-generated long single-stranded DNA (ssDNA). As there are hundreds of DNA probes on the nanoprobe, one hybridization event would generate hundreds of long ssDNA. Then specific binding of Av-HRP to the biotin label leads to an enzyme turnover-based signal transduction. By employing nanoprobe and TdT, we aim to provide a novel E-DNA sensor with high femtomolar sensitivity and excellent differentiation ability for even single mismatches.

# Electrochemical Characterization of Gold-Coated Magnetic Nanoparticles as ‘Dispersible Electrodes’

Saimon Moraes Silva, Roya Tavallaie, Muhammed Alam, J. Justin Gooding

School of Chemistry and Australian Centre for NanoMedicine, The University of New South Wales  
Sydney 2052, Australia

[s.silva@student.unsw.edu.au](mailto:s.silva@student.unsw.edu.au), [justin.gooding@unsw.edu.au](mailto:justin.gooding@unsw.edu.au)

The ‘Dispersible Electrodes’ concept was previously introduced in our group by Goon *et. al.* as an electrochemical approach to detect extreme low concentration of analyte in large samples volumes in a reasonable time frame.<sup>1, 2</sup> In this concept, the electrochemical sensor is subdivided in minute pieces by using conducting gold coated magnetic nanoparticles (Au@MNPs) as active element in the selective capture and direct electroanalytical quantification of the species of interest.<sup>1</sup> The Au@MNPs are dispersed in solution,

**Figure 1** – Outline of the basics steps necessary for the measurement of a target analyte using the Dispersible Electrodes.

once the capturing process has completed a magnetic field is applied and brings the nanoparticles to the sensing interface to the electrochemical measurements (Figure 1). So far, the Au@MNPs that has been used in this approach is on average 150 nm in size and exquisite results have been achieved with them.<sup>3</sup> However, with a view to obtain improved monodispersity and stability against aggregation, the present work evaluates the synthetic route and the electrochemical properties of different types of Au@MNPs for its application as ‘Dispersible Electrodes’. The obtaining of stable, monodisperse, well-defined, and nanoparticles that are fully coated with gold are crucial to understand how the particles assemble in the sensor interface and how they interact with the analyte. The Au@MNPs proposed in our group by Goon *et. al.* was used as the model particles, this kind of particles have a ill-defined shape but exhibited excellent magnetic properties.<sup>3</sup> A second type of spherical particles was studied, which are henceforth referred to as Gao-Au@MNPs because the synthesis was performed according to a procedure reported by Gao and co-workers.<sup>4</sup> The third kind of particles was synthesized according to a procedure reported by Freitas *et. al.*,<sup>5</sup> so called Freitas-Au@MNPs. Finally, cubic Au@MNPs (Cubic-Au@MNPs) were obtained by using the iron oxide cores coated with polyethylenimine according to procedure reported by Goon and co-workers<sup>3</sup> and the gold nanoshell was formed by reducing gold chloride with a reducing agent. The four types of particles were characterized morphologically by using Transmission Electron Microscopy, Scanning Electron Microscopy and X-Ray Photoelectron Spectroscopy. The success of the fully gold coating of the different Au@MNPs was accessed by using cyclic voltammetry in 50 mM H<sub>2</sub>SO<sub>4</sub> solution in comparison to a polycrystalline gold electrode. All the four types of particles were stable in the acid medium even after 100 scans. The kinetics of electron transfer and how the Au@MNPs assemble in the bulk electrode were investigated by using techniques such as cyclic voltammetry and impedance and also different electrochemical probes such as potassium ferricyanide, ruthenium hexamine and cobalt-phenanthroline. The four types of particles presented different behaviours that is discussed in this current work and each of them presents positive and negatives features for its applications as ‘Dispersible Electrodes’. We are still looking for improvements in the synthesis of the Au@MNPs so we can have a better defined system to investigate.

In seawater, cathodic protection (CP) of metallic structures leads to the formation of calcareous deposits. This phenomenon depends on a lot of parameters, which have given origin to numerous researches for several years: applied potential, substrate nature, flow rate, temperature, pH, pressure or seawater composition influences have been extensively studied in artificial and natural seawaters. Recently, a new method based on an innovative adaptation of cathodic protection technique has been developed in order to synthesise in volume the calcareous structures in natural seawater. Our objective, in the context of the Research National Agency (ANR) EcoCorail project, is to favour conditions to a rapid 3D deposit growth, predominantly composed of  $\text{CaCO}_3$ . This calcareous conglomerate could be used as “natural cement” linked with sand, shells, marine sediments, etc. to create a natural concrete. This method needs to apply more cathodic potentials than those used in CP, corresponding to the range of potential of hydrogen evolution, in order to prevent the cathode blocking, and to induce pH increased far away from the electrode.

The influence of applied potential and temperature on properties of calcareous deposit has previously been studied [1]. It was shown that brucite is predominantly observed ( $> 90$  at%) with high deposition rate for high cathodic potentials ( $-1.2$ ;  $-1.3$  V vs.  $\text{Ag}|\text{AgCl}_{\text{sat}}$ ) and acts as an aragonite's growth inhibitor. A temperature decrease deactivates hydrogen evolution and reduces the pH favouring aragonite formation. For less negative potentials ( $-1.0$ ;  $-1.1$  V vs.  $\text{Ag}|\text{AgCl}_{\text{sat}}$ ), deposit growth is very low. In all experiments, calcite is only present at very small ratio, typically lower than a few percent.

The present study focuses on the influence of the two-step applied potentials on the deposition and structure of calcareous formed. Experiments are designed to form volume calcareous deposits on immersed carbon steel grids in natural seawater with deposition time varied from 2 to 30 days. In order to simulate a natural environment, experiments are led with natural seawater directly pumped from the sea into a  $0.9 \text{ m}^3$  tank at the Marine Station of Luc-sur-Mer (Channel coast of France). The temperature is fixed at  $20^\circ\text{C}$ . Four different series were carried out with a first step of applied potential  $E_1$  fixed at  $-1.3$  V vs.  $\text{Ag}|\text{AgCl}_{\text{sat}}$ . The second step of applied potential ( $E_2$ ) is fixed successively at  $-1.1$ ;  $-1.0$ ;  $-0.9$  V vs.  $\text{Ag}|\text{AgCl}_{\text{sat}}$  or open circuit potential–OCP for each experiment. Different periods for both steps were tested.

Two-step potential waveform influences the chronoamperometric curves. Deposit weights, structures and microstructures are followed using electrochemical impedance spectroscopy (EIS), scanning electron microscopy (SEM), transmission electron microscopy (TEM) and X-ray diffraction. XRD patterns analysed using the combined analysis methodology allow the quantitative determination of phase fractions, cell parameters, atomic positions and mean anisotropic crystallite sizes for each phase. Our results show that the two-step potential waveform permits to maintain a high rate of calcareous deposition and so favours to form rapidly the 3D calcareous deposits. The second step  $E_2$  (especially at  $-0.9$  V vs.  $\text{Ag}|\text{AgCl}_{\text{sat}}$ ; OCP) plays an important role to increase significantly the proportion of  $\text{CaCO}_3$  present in the deposit to about 30-50 at%.

An electrolytic reduction process has been developed to produce pure metals from their oxides through an electrochemical reaction using molten salt electrolyte [1]. An electrolytic reduction is essential in pyroprocessing, in which the spent oxide fuels used in current nuclear reactors are recycled into metallic fuels for the next-generation fast reactors [2]. High-temperature O<sub>2</sub> gas is evolved in the anode during the electrolytic reduction, and therefore, the anode material should be stable in this highly oxidizing atmosphere. Pt is the common anode material owing to its excellent oxidation resistance. However, Pt can be damaged during the electrochemical reaction in a LiCl-Li<sub>2</sub>O electrolyte, which is widely used in the electrochemical reduction of UO<sub>2</sub> in the pyroprocessing [3].

In this study, we investigated the feasibility of conductive ceramics as O<sub>2</sub>-evolving anodes because they are considered to be more stable than metals or their alloys in an oxidizing atmosphere. Several conductive ceramics were able to electrochemically reduce UO<sub>2</sub> into metallic U with an O<sub>2</sub> evolution, showing the potential of conductive ceramic anodes.

# Does a link between multiple oxidation peaks of gold oxide formation and exposed crystal planes exist on polycrystalline gold?

C. Jeyabharathi, P. Ahrens, U. Hasse and F. Scholz

*Institute of Biochemistry, University of Greifswald,  
Felix-Hausdorff-Str.4, 17487 Greifswald, Germany

## ABSTRACT

Though monolayer oxidation on single crystal gold surfaces are well studied and crystal planes can be distinguished based on the peak potential of oxide formation, to the best of our knowledge, no paper relates the multiple oxide peaks on polycrystalline gold to crystal planes. In this work, we cycled the gold electrode in  $\text{H}_2\text{SO}_4$  and hydrochloric acid solutions and tried to link the CV features to crystal planes. Electrochemically cycling of gold electrode in 0.1 M  $\text{H}_2\text{SO}_4$  shows that the as-polished gold surface has a broad peak centered at 1.33 V vs Ag/AgCl (3 M KCl), whereas the surface after electrochemical cycling for 50 runs exhibited three distinct peaks in the monolayer-oxide region, those could be related to the oxide formation on different crystal planes. However, cycling in 0.1 M hydrochloric acid solution shows a sharp peak at 1.35 V initially, and a highly intense peak at 1.12 V during consequent potential cycles at the cost of a peak at 1.35 V (Fig 1a). These features can be ascribed to the preferential orientation or faceting of the gold surface during dissolution and re-deposition cycles. The activity of the surface to the ORR is less in terms of half-wave potential ( $E_{1/2}$ ) when the peak current at 1.35 V is higher than that of the one at 1.12 V. After prolonged cycling, the shift of ORR peak to more positive  $E_{1/2}$  values (Fig 1b) is observed, when the peak at 1.12 V gets larger than the one at 1.35 V. Such a transition can be attributed to changes in the surface structure. When comparing with the peak potentials of monolayer oxidation on single crystal electrodes [J.Phys.Chem.C, 2007, 111, 13197], we can attribute the peak at 1.35 V to the (111) plane and the one at 1.12 V to the (100) plane. The observed ORR activity is also in accordance with the trend given in literature: (100) > (110) > (111). The changes in the double layer capacitance due to reconstruction of the surface and its lifting in addition with the above results suggest that there is a clear link between the oxide formation peaks on polycrystalline gold to single crystal planes.

# Concentration Rectification in Nanofluidic Transducers

Jin Cui, Klaus Mathwig, Serge G. Lemay  
MESA+ Institute for Nanotechnology, University of Twente  
Enschede, The Netherlands  
j.cui-1@utwente.nl

We are incorporating microfluidic fluid flow control with redox-cycling based nanogap bioelectrochemical transducers. This allows deterministic mass transport across multiple transducers located downstream for each other, even near or at the single-molecule limit. We introduced earlier electrical cross-correlation spectroscopy to detect molecule-number fluctuations in nanofluidic channels by cross-correlating steady-state electrochemical signals between pairs of electrodes located upstream and downstream from each other.<sup>1</sup> Surprisingly, the transient change in signal at a downstream electrode pair in response to switching of the potential at an upstream electrode cannot be explained exclusively in terms of processes taking place at the upstream electrode.<sup>2</sup> This effect persists in the presence of high concentrations of supporting electrolyte and is thus not purely electrostatic in nature. We argue that it instead results from concentration enhancement-depletion effects tied to unequal effective diffusion coefficients for the analyte molecules in different redox states.<sup>3</sup> The observed nonlocality is thus closely related to so-called rectifying behavior in nanofluidic diodes,<sup>4</sup> with the added element that here redox chemistry provides the required breaking of symmetry between cation and anion flow. The experiments can be understood qualitatively in terms of the Péclet number in the nanochannel, and lead to new insights into the effect of longitudinal diffusion under fluid flow in electrochemical nanofluidics.

Figure 1 (Top) two nanogap transducers coupled via a microchannel and a nanochannel connected in parallel. (Bottom) The solid line represents the experimental amperometric signal from a downstream transducer in response to stepping the potential of the upstream electrode. Surprisingly, the downstream steady-state current is influenced by the remote upstream electrodes. The dashed line is a simulated result obtained by solving the coupled equations for convection of the solvent and diffusion of the redox species. The simulation, which assumes bulk values for the diffusion constants of reduced and oxidized molecules ( $6.7 \times 10^{-10} \text{ m}^2/\text{s}$  and  $5.36 \times 10^{-10} \text{ m}^2/\text{s}$ , respectively) captures the main features of the experimental observations.

There are special heat transfer properties in carbon nanotube due the high aspect of surface area to volume. Carbon nanotube can be used as the filling stuff of composite materials or nanofluid to enhance their thermal performances. This paper investigates the difference of heat transfer characteristics of carbon nanotube from bulk material to improve the thermal transport performance. Using nanoscale thermal transport model, this paper analyzes heat transfer characteristics of carbon nanotube and compares the predicted result with the available experimental data. The effects of parameters on heat transfer characteristics in the carbon nanotube are also discussed.

Temperature profile along the nanotube for different Knudsen numbers

# Multilayer Deposition of Iridium Oxide for Biocompatible Stimulating Electrode Application

<sup>a</sup>Pu-Wei Wu, <sup>a</sup>Chai-Wei Chung, <sup>a</sup>Yong-Min Chen, <sup>b</sup>Po-Chun Chen\*

<sup>a</sup>*Department of Materials Science and Engineering, National Chiao Tung University, Hsinchu 300, Taiwan, R.O.C.*

<sup>b</sup>*Biomedical Electronics Translational Research Center, National Chiao Tung University, Hsinchu 300, Taiwan, R.O.C.*

[\\*pcchen@g2.nctu.edu.tw](mailto:pcchen@g2.nctu.edu.tw)

Iridium oxide has received substantial attention in recent years because of its unique ability to inject electric charge and its resistance to corrosion. Moreover, this metal oxide is formed with ionic bonds and the hybridized s orbitals are fully occupied with electrons, which lead to notable stability in both thermal and chemical properties. In this study, we carry out a multilayer deposition of IrO<sub>2</sub> film via chemical bath process. IrO<sub>2</sub> film (CIROF) is successfully fabricated via multi-step deposition with heat treatment, and it is expected to be used as a biocompatible stimulating electrode. The multilayer CIROF is characterized its morphology, composition, crystallinity, surface roughness by SEM, XPS, XRD, and contact angle, respectively. In addition, the conductivity and stimulating performance of the CIROF are employed by Hall Effect and electrochemical measurements following ISO-10993.

# Manufacturing of Micro Probe Tip through Ni Alloys Electroplating

Joo-Yul Lee, Yongsoo Jeong

*Korea Institute of Materials Science*

*797 Changwondaero, Seongsangu, Changwon, Gyeongnam, 642-831, Korea*

*leeact@kims.re.kr*

Electroplating through thick photoresist made it possible to manufacture three dimensional metallic features precisely for the electronic parts. The most popular metallic microstructure is made of nickel sulfamate bath. However, the strength of the as-plated nickel is insufficient, and needs to be hardened through alloying with other elements such as Mn, Co, B, P and so on followed by post-annealing process. We developed new nickel alloy plating solutions to cope with the necessity for monitoring the electrical characteristics of more precise metallic circuits and architecture with narrow line and space. We manufactured photoresist mold on the silicon wafer surface after the shape of micro probe tip array using spin coating and some semiconductor fabrication unit process. Probe tip was electroplated at different alloy composition and additives, and underwent annealing process in the oxygen free atmosphere at 300°C for one hour to endow hard surface characteristics. We also observed the effect of surface modification on the electrical properties of probe tips.

[Fig.1] Electrostatic properties of Ni alloy probe Tips

# Electrochromic Copolymer Film Deposition for Visualization of Latent Fingerprints on Stainless Steel Surfaces

A. Robert Hillman, Rachel M. Sapstead, Natalie Corden and Emma J. R. Palin  
University of Leicester, Leicester LE1 7RH, UK  
e-mail: arh7@le.ac.uk

The pattern of friction skin ridges on the fingertips of an individual is unique. Contact between the finger and an object results in the transfer of material between the finger and the surface in a manner determined by this fingerprint ridge pattern, thereby unambiguously demonstrating that the individual was in that location (for a fixed entity, such as a fixture in a building) or handled that object (in the case of a moveable entity, such as a weapon or tool). This principle is widely exploited in criminal investigations to link people, objects and locations.

In cases where the transferred material is coloured – including blood, ink, paint or foodstuff – the image is immediately visible, irrespective of whether transfer is from the finger to the surface (creating a positive image) or from the surface to the finger (leaving a negative image). Such images are readily seen by the individual and thus commonly removed ("wiped"). However, even in the absence of such foreign substances, there is transfer of fingerprint sweat to the surface, resulting in a non-visible fingerprint image. These *latent* marks are the predominant source of fingerprint evidence at a crime scene: the challenge is to make them visible. Innumerable procedures and reagents (powders, dyes, cyanoacrylate) have been developed to interact with the *fingerprint residue*, but their utility is limited by loss of residue due to environmental exposure. For the case of metallic objects, we have adopted a complementary strategy, in which the fingerprint residue acts as a template to direct electrochemically generated reagent to the *bare surface* between the deposited ridges.

The basic templating concept was recently demonstrated using electrodeposited polyaniline [1] and PEDOT [2] films. These materials have electrochromic properties so, after transfer to background electrolyte, the applied potential can be used to vary the optical properties (simplistically "colour") of the films to optimize visual contrast with the substrate. Here we extend the concept to copolymer films, with the aim of expanding the range of colours available. Building upon the previous polyaniline study [1], we use co-monomers based on aniline and pyrrole. As substrate, we consider stainless steel, a material of forensic relevance in terms of weapons (e.g. knife crime) and tools.

The first stage is establishment of relative growth rates under different conditions (potential, control function, electrolyte). In the case of polypyrrole, new homopolymer enhanced latent fingerprint images are acquired, complementing those available for polyaniline enhancement [1]. The ability of polypyrrole to reveal fingermarks on surfaces subject to a range of environmental conditions (notably heat and water exposure) is promising. Based on these data for the homopolymers, we identify compromise conditions and co-monomer concentration ratios under which co-polymers containing significant fractions of both monomers can be deposited and for which the films are stable.

Spectroelectrochemical characterization of the resulting co-polymers and fingerprint images was then pursued at two levels. Digital optical images were split into their *RGB* components; this is a simple procedure giving improved visualization without complex instrumentation. More detailed FTIR spectroscopic analysis of poly(pyrrole-co-aniline) is complicated by the presence of similar functionalities in the two monomers. We therefore explored the polymerization of 1-(2-cyanoethyl)pyrrole and of a dansyl-functionalised aniline. The former provided a characteristic cyano functionality, readily identified in the FTIR spectrum, and the latter holds the prospect – to be exploited – of a fluorescent electrochromic material.

# Minimal instrumentation electroanalytical experimental approach

Arturo García-Mendoza, Adrián de Santiago, Alejandro Baeza\*  
Departamento de Química Analítica, Facultad de Química, UNAM  
Ciudad Universitaria, 04510, Mexico. D.F.  
baeza@unam.mx

Nowadays commercial instruments are becoming increasingly more sophisticated and the user interfaces are simpler and sleeker, leading many teachers to believe that the essential or professional educational objective is to know how to “insert” a sample, learn the instrument software and how performing many assays in few time. Regrettably many instruments have become in “black boxes” that frequently students never appreciate because of they do not realize the real physicochemical principle of the technique, the practical limitations over the instrument design and data acquisition nor the aspects that influence the significance or quality of the data.

In our laboratory we have developed low cost equipment with local materials to perform potentiometric, conductimetric, coulometric, electrochemical and photocolormetric measurements to teach Instrumental Analytical Chemistry focusing in the principles of each technique, the minimal instrumentation necessary and the data acquisition details using available digital low cost devices [1-3] Good analytical results have been achieved in undergraduate and graduate courses in most of Chemistry Colleges in México, some ones in Center and South America or even Europe, in a period of at least eleven years. In some of the latter universities, the methodology presented has given them their first opportunity to achieve electrochemical experimental approach.

Fig. 1 shows the minimal instrumentation equipment built with low-cost local available materials to perform, (a) ISE potentiometric, (b) conductimetric, (c) voltammetric and (d) photocolormetric determinations in several applied fields as clinic, foods analyses, environmental and pharmaceutical, with statistically acceptable analytical results. Fig. 2 shows typical plots obtained with our equipment.

**Fig. 1** Low cost minimal instrumentation designed in our laboratory.

**Fig. 2** Typical records obtained with low-cost equipment. Assay specifications are displayed as inserts.

# Construction and evaluation of reference electrodes for imidazolium-based ionic liquids. An analytical description.

Arturo García-Mendoza, Julio C. Aguilar

*Departamento de Química Analítica, Facultad de Química, UNAM*

*Ciudad Universitaria, 04510, Mexico. D.F.*

*julioca@unam.mx*

Notwithstanding the increasing importance of ionic liquids (IL) in electrochemical studies and applications, true reference electrodes (RE) are not readily available for its use in these media, and potential scales in IL are scarce. Furthermore, electrochemical assays with quasireference electrodes are not suitable for establishing such scales, since the quasireference electrode potential greatly depends on the composition of the sample and on the state of its surface [1].

In this study, the construction of twelve RE for the aprotic ionic liquids (AIL) [C<sub>2</sub>mim][NTf<sub>2</sub>], [C<sub>3</sub>mim][NTf<sub>2</sub>] and [C<sub>2</sub>mmim][NTf<sub>2</sub>], as well as eight RE for the protic ionic liquid (PIL) [C<sub>2</sub>Him][NTf<sub>2</sub>] (C<sub>2</sub>mim = 1-ethyl-3-methylimidazolium, C<sub>3</sub>mim = 1-propyl-3-methylimidazolium, C<sub>2</sub>mmim = 1-ethyl-2,3-dimethylimidazolium, C<sub>2</sub>Him = 1-ethylimidazolium, NTf<sub>2</sub> = bis(trifluoromethanesulfonyl)imide), is reported and the stability of their electrode potential values for at least nine months was determined by cyclic voltammetry (CV) of the cobaltocenium cation, Cc<sup>+</sup>, and ferrocene, Fc. The electrode potential stability studies were carried out on gold, platinum and glassy carbon working electrodes (WE). The cobaltocenium/cobaltocene redox couple, Cc<sup>+0</sup>, is an important redox system commonly used as internal standard for calibration of RE in IL. The ferricenium/ferrocene couple, Fc<sup>0/+</sup>, commonly used as a standard redox system, was only used when Cc<sup>+0</sup> was not suitable for analysis, since some experimental drawbacks have been previously reported [2], related with the chemical stability, volatility and to the concentration dependence of the diffusion coefficient of ferrocene [2,3].

The RE Ag|AgCl|[C<sub>2</sub>mim][Cl] (IL)|| were prepared following in glass tubes sealed with Vycor® glass. The RE were filled with an internal solution of [C<sub>2</sub>mim][Cl] in each IL giving different concentration of chloride, and then they were stored for five days before their first use. All measurements were performed under N<sub>2(g)</sub> in a glass cell. A Pt wire was used as a counter electrode and each IL was dried for 24 hours at 90° C. The water content in the IL after drying was determined by cathodic stripping square wave voltammetry (CSSWV) at a gold electrode and it was usually found < 180 ppm for all three AIL and > 350 ppm for the PIL. The time evolution of the potential of the RE was followed using [Cc][PF<sub>6</sub>], in all three AIL, or Fc, in the PIL, as internal standards. Individual CV studies of the Cc<sup>+</sup> ion in any of the RE regardless showed a reversible behaviour, following a linear proportional relationship to both the square root of the scan rate and concentration. Diffusion coefficients were calculated with the Randles-Sevcik relationship, and their values are comparable to previously reported data [4]. The standard electron transfer rate constant, k<sup>0</sup>, was also estimated by an alternative method [5]. In order to describe the process associated to the electrode potential in the interphase metal-solution, potentiometric assays in solutions of [C<sub>2</sub>mim]Cl or Ag[NTf<sub>2</sub>] were carried out. A Nernstian relationship was found for Ag or Ag|AgCl electrodes in a cell using the best RE previously described. These results suggest the formation of [AgCl<sub>n</sub>]<sup>1-n</sup> species in these IL.

Electric double-layer capacitor (EDLC) is an energy storage device that accumulates electric charges in an interphase between an activated carbon electrode and an electrolyte. Tetraethylammonium tetrafluoroborate (TEABF<sub>4</sub>) or triethyltetraethylammonium tetrafluoroborate (TEMABF<sub>4</sub>) is commonly used as the single electrolyte for EDLCs. Propylene carbonate (PC) is commonly used as the single solvent for EDLCs. The use of moderately high concentrations of electrolytes can improve both the concentration of charge carriers and the availability of pores. There are two approaches to the realization of highly concentrated and conductive solutions containing electrolytes: designs for electrolytes and solvents. The solubility of tetramethylammonium difluoro(oxalato)borate (TMADFOB) in PC was 2 M (M = mol dm<sup>-3</sup>) or more at 25 °C. In contrast, the solubility of tetramethylammonium tetrafluoroborate (TMABF<sub>4</sub>) is as low as 0.1 M at 25 °C. The solubility of TEABF<sub>4</sub> in PC is about 1.1 M at 25 °C, whereas that of TEMABF<sub>4</sub> is 2.2-2.3 M at 25 °C. The maximal electrolytic conductivity of a TMADFOB solution in PC was observed at about 1.6 M at 25 °C.

The determination of double-layer capacitance is essential for the evaluation of the performance of EDLCs. The potential-time plot resulting from a current step gives a straight line for a simple RC series circuit. One can roughly estimate the double-layer capacitance from the reciprocal of the slope of the similarity line. However, the experimental data for the charge and discharge of EDLCs do not follow the straight lines, but show slightly curved ones.

We have derived theoretical equation for a constant-current (CC) charge or discharge. The equivalent circuit of the average pore of an activated carbon electrode is represented by use of a transmission-line network of finite length. The theoretical treatment involves double-layer capacitances at the opposite end of the pore as well as on the electrode surface. The equation we derived has enough flexibility to show the effect of double-layer capacitance on the length and shape of a single pore.

$$-\Phi_{\text{max}}(\tau) = -\Phi_1 + 1 + \frac{\gamma^2}{6(\theta^2 + \gamma^2(1 + \zeta^2))} [6(\theta^2 + \gamma^2(1 + \zeta^2)) \tau + 3(\theta^2 + \gamma^2(1 + \zeta^2))(\theta^2 + 2\gamma^2\zeta^2) - \{6\gamma^4\zeta^2 + \theta^4 + 3\gamma^2\theta^2(1 + \zeta^2)\}] \quad (1)$$

$$\tan \alpha_n + \frac{\gamma^2\theta^2\alpha_n(1 + \zeta^2)}{\theta^4 - \gamma^4\zeta^2\alpha_n^2} = 0 \quad (2)$$

$$-2\gamma^2\theta^2 \sum_{n=1}^{\infty} \frac{\alpha_n^2}{\alpha_n^4 \{[-\gamma^4\zeta^2\alpha_n^2 + \theta^4 + \gamma^2\theta^2(1 + \zeta^2)] \cos \alpha_n - \alpha_n \{ \gamma^2\theta^2(1 + \zeta^2) + 2\gamma^4\zeta^2 \} \sin \alpha_n \}} \exp\left(-\frac{\alpha_n^2 \tau}{\theta^2}\right)$$

Here  $\theta^2 (= R_l C_l^2 / R_s C_s)$  denotes the time constant ratio of a pore to an electrode surface.  $\gamma^2 (= R_l / R_s)$  stands for the resistance ratio of a pore to the bulk of a solution.  $\zeta^2 (= C_e / C_s)$  represents the double-layer capacitance ratio of the closed end of a single pore to an electrode surface. Accordingly,  $(\theta / \gamma)^2 (= C_l / C_s)$  and  $\zeta^2 (= C_e / C_s)$  show the effect of the double-layer capacitance on the length and shape of a single pore, respectively.  $\zeta^2 = 1$ ,  $\zeta^2 = 0$ , and  $\zeta^2 \gg 1$  may correspond to a cylinder, a cone, and a reverse cone, respectively.

The theoretical cell voltage-time curves were fitted to experimental data for the discharge of EDLCs. Figure 1 compares theoretical and experimental cell voltage ( $U_{\text{cell}}(t)$ )–time ( $t$ ) behavior resulting from a CC discharge. The initial electric-potential difference between an electrode and a solution phases ( $E_i$ ) was taken as 2.5 V. The experimental discharge curves of 2025-type coin cells were obtained by use of (a) 1.6 M TMADFOB and (b) 1.6 M TEMABF<sub>4</sub> solutions in PC. They were used as single electrolytes. Current and cut-off voltage during the CC discharge were set to 1.33 mA ( $= I_{\text{appl}}$ ) (1 mA cm<sup>-2</sup>) and 0 V, respectively. The increase in the concentration of the electrolyte resulted in the increase in the capacitance. The capacitance and resistance found for TMADFOB ( $C_l = 0.80$  F and  $R_l = 100$  Ω) was slightly higher than that for TEMABF<sub>4</sub> ( $C_l = 0.77$  F and  $R_l = 83$  Ω). A very small distance between activated carbon electrodes in the coin cell can compensate for the lower ionic mobility of TMADFOB in the bulk of a PC solution. Furthermore, TMA<sup>+</sup> and DFOB<sup>-</sup> may more closely approach the electrode in a compact double layer.

# Electrochemical CO<sub>2</sub> Reduction in EMIM-TFSI Ionic Liquid

Kazuhisa Azumi, Hayato Yoshikawa, Kazunori Suetake  
Graduate School of Engineering, Hokkaido University  
N13W8, Kitaku, Sapporo, Japan  
azumi@eng.hokudai.ac.jp

Reduction of CO<sub>2</sub> gas using natural energy resource to produce useful chemicals has been an important issue to establish the sustainable society. Some of ionic liquid such as 1-ethylimidazoliumbis(trifluoromethylsulfonyl)imide (EMIM-TFSI) ionic liquid (I.L.) is known to absorb CO<sub>2</sub> gas and thus considered as a medium for CO<sub>2</sub> gas separation. In this study EMIM-TFSI was used for electrolyte solution in which CO<sub>2</sub> gas is electrochemically reduced to form, for example, methane. EMIM-TFSI is also an hydrophobic liquid and thus water content is limited to be low level. This means that the sub-reaction of electrochemical CO<sub>2</sub> reduction such as water decomposition can be suppressed. In the experiments a small two-compartment electrochemical cell composed of a room filled with I.L. and another room filled with KCl solution was used (**Fig.1**). Two rooms were separated with a Nafion membrane to allow proton transportation between two rooms. CO<sub>2</sub> gas was bubbled in the I.L. bath and cathodically reduced on Cu working electrode (WE). The ambient gas in the cell was then induced to gas sensors to analyze the reduction products. In the another room the counter reaction of water decomposition (oxygen evolution reaction) was proceeded on a Pt-counter electrode (CE). The protons were formed in this reaction and supplied to the I.L. room *via* proton conducting Nafion membrane. If a single compartment cell was used, I.L. was decomposed on the CE in the water-poor medium. **Fig. 2** shows change in voltammogram of Cu-WE in the EMIM-TFSI-I.L. bath as a function of water content and CO<sub>2</sub> gas injection. Fig. 2 shows clearly that both of water and CO<sub>2</sub> gas were necessary to cause CO<sub>2</sub> reduction reaction at the potential lower than -1.4 V. Cathodic current showed clear response to changing the flow gas between Ar and CO<sub>2</sub> as shown in **Fig. 3**. Gas analysis using gas chromatography revealed that the optimized water content for efficient CO<sub>2</sub> reduction to form methane was ca. 5000 ppm.

**Fig. 1.** Two compartment cell used for electrochemical CO<sub>2</sub> reduction.

**Fig. 2.** Dependence of CV curves of Cu-WE in EMIM-TFSI I.L. bath as a function of CO<sub>2</sub> gas and water content.

**Fig. 3.** Transition of cathodic current at -1.6 V in the CV changing with flow gas between Ar and CO<sub>2</sub>.

# Relative Permittivities of Binary Solvent Mixtures

Masaru Ogasawara, Shohei Suzuki, and Noritoshi Nambu  
*Department of Life Science and Sustainable Chemistry,  
 Faculty of Engineering, Tokyo Polytechnic University  
 1583 Iiyama, Atsugi, Kanagawa 243-0297, Japan  
 nanbu@chem.t-kougei.ac.jp*

Binary solvent mixtures exist as liquids over a wide range of temperatures and pressures. For the rational use of the solvent mixtures it is essential to know their physical and chemical properties as functions of their composition and the ambience. Relative static permittivity ( $\epsilon_r$ ) reflects the ease of dielectric polarization. The relative permittivity is a measure of the solvent's ability to insulate opposite charges from each other and has a very significant effect on the strength of the interactions between ions especially in dilute solutions. Electrostatic attractions and repulsions between ions are smaller in solvents with higher relative permittivities.

Assuming the triangular configurations ( $ijk$ ) in a liquid state and a first approximation for the number of molecular configurations, we have derived the equation for the dependence of relative permittivity ( $\epsilon_{r \text{ soln}}$ ) on the composition of a binary solvent mixture ( $x_2$ ).

$$\epsilon_{r \text{ soln}} \approx \epsilon_{r111}(1-x_2) + \epsilon_{r222}x_2 + 3\Delta\epsilon_{r112}\bar{\zeta}_t + 3\Delta\epsilon_{r122}\bar{\zeta}_t \quad (1)$$

$$\bar{\zeta}_t = \frac{x_2}{\eta_t^{2-\alpha} \rho_t^2 + 2\rho_t + 1} = \frac{\rho_t(1-x_2)}{\eta_t^{2\alpha-1} + 2\rho_t + \rho_t^2} \quad (2)$$

$$\rho_t = \frac{\bar{\zeta}_t}{\zeta_t} \quad (3)$$

Based on the random distribution of the solvent molecules, the equation (1) can be simplified in the following manner.

$$\epsilon_{r \text{ soln}} \approx \epsilon_{r111}(1-x_2) + \epsilon_{r222}x_2 + 3x_2(1-x_2)\{\Delta\epsilon_{r112}(1-x_2) + \Delta\epsilon_{r122}x_2\} \quad (4)$$

Here  $\Delta\epsilon_{r112}$  and  $\Delta\epsilon_{r122}$  may be related to the dipole moments, the polarizabilities, and the angular correlations between the dipoles. The equation (4) is similar to an empirical representation of relative permittivity with polynomials of the molar fraction.

Figure 1 shows the relative permittivities ( $\epsilon_{r \text{ soln}}$ ) of a binary mixture of ethylene carbonate (EC) and 2-fluoroethyl methyl carbonate (2FEMC) and a binary mixture of EC and ethyl methyl carbonate (EMC) at 25 °C as a function of composition. The symbol  $x_2$  denotes the molar fraction of a low-viscosity solvent (2FEMC or EMC). EC is a cyclic carbonate, whereas 2FEMC and EMC are linear carbonates. EC and EMC are commonly used as high-polarity and low-viscosity solvents for lithium-ion batteries, respectively. The equation for the composition dependence of the relative permittivity fitted experimental data. The relative permittivity of the EC–2FEMC binary mixture was higher than that of the EC–EMC counterpart. The value of  $\Delta\epsilon_{r122}$  found in the EC–2FEMC binary solvent system (–14.0) was less negative than that in the EC–EMC binary solvent system (–16.5). These findings suggest that dipole moments associated with 2FEMC molecules add vectorially to larger values and that linear but short chain structures predominate in the solution containing a large amount of 2FEMC. The attraction of 2FEMC molecules can be based on nonconventional weak intermolecular hydrogen bonding ( $\text{CF-H}\cdots\text{O=C}$  or  $\text{C-H}\cdots\text{F-C}$ ) as well as conventional dipole-dipole interactions. The weak hydrogen-bonding system does not exchange its proton and therefore it is no more a genuine hydrogen bond; it is an electrostatic attraction of positive charge on the hydrogen and negative charge on the organic fluorine or the organic oxygen.

**Fig. 1** Relative permittivities ( $\epsilon_{r \text{ soln}}$ ) of EC–2FEMC and EC–EMC binary mixtures at 25 °C as a function of composition. The symbol  $x_2$  represents the molar fraction of a low-viscosity solvent (2FEMC or EMC).

# Reverse Electrodialysis (RED) as a New Electrical Power Source for a Drug Delivery System

Seung-Ryong Kwon, Sung Yul Lim, and Taek Dong Chung\*

*Department of Chemistry, Seoul National University*

*Gwanak-ro 599, Gwanak-gu, Seoul 151-747, Korea*

*tdchung@snu.ac.kr*

Reverse electrodialysis (RED) is one of the promising technologies for generating eco-friendly electrical power from renewable energy resources. In the early 1950s, Pattle demonstrated the production of electrical power by mixing the fresh water with sea water which are continual resources at estuaries for the first time [1]. When a semi-permeable membrane presents between solutions with different salinity concentrations (e.g., sea and river water), a defined voltage can be gained as a result of selective transports of ions from higher concentration to lower one. However, this process had not been fairly considered as a potential alternative to conventional power sources before we seriously faced the depletion crisis of natural resources. Recently, a couple of European countries, including Netherland, Italy, and Norway, have been interested in development of the electricity production systems based on salinity gradient. Meanwhile, some scientists paid attention eco-friendly and readily combinable RED systems with other technologies for unique applications. Logan group at Pennsylvania State University showed an interesting strategy for the greatly increased electricity production ( $5.6 \text{ W/m}^2$ ) with simultaneous waste water purification using the hybrid system of RED and microbial cell [2]. They also demonstrated the hydrogen production process using the generated electricity in the same combinations [3]. In this presentation, a drug delivery system based on RED as a new electrical power source is introduced and discussed.

<sup>1\*</sup>[h-shiroishi@tokyo-ct.ac.jp](mailto:h-shiroishi@tokyo-ct.ac.jp)

## 1. Introduction

A new low-cost electrolyte is expected to be developed for polymer electrolyte fuel cells (PEFCs) because conventional perfluorosulfonate polymers (e.g. Nafion<sup>®</sup>) with high proton conductivity ( $0.1 \text{ S cm}^{-1}$ ) and excellent chemical stability are expensive. In this report, nano particle-type new proton conductors (NPPCs) has been synthesized by a hydrothermal method with a d-glucose solution followed by the introduction of sulfonic acid groups.

## 2. Experimental

50 mL of 0.5 M d-glucose aqueous solution was hydrothermally-treated at 193°C for 6 h to produce nano-carbon particles, followed by washing with acetone and Milli-Q water and drying in vacuum. The obtained powders were refluxed in 9-18 M  $\text{H}_2\text{SO}_4$  aqueous solution for 7.5-24 h to introduce sulfonic acid groups; the following washing with Milli-Q water and drying in vacuum produced NPPCs powders (sample names were denoted by "NPPC-[reflux time]-[concentration of sulfuric acid]"). The NPPCs powders were characterized by FE-SEM (Quanta 250 FEG, FEI), acid base titration, and TG/DTA (TG-DTA2500, NETZSCH)-GC/MS (GCMS-QP2010 Ultra, SHIMADZU). The bulk proton conductivity of NPPC pellets sputtered with Au electrode, which was prepared by pressing NPPC powders mixed with 25 wt% PTFE powder (TFW3000F, Seishin Enterprise) at 46 MPa, was measured with AC impedance analyzer (4192A, HP); the frequency and temperature were varied between 5 Hz-13 MHz and 80-200°C, respectively, with an applied voltage of 0.05 V under 10 mol%  $\text{H}_2\text{O-N}_2$  atmosphere.

## 3. Results and Discussion

The yield of nano-carbon particles was about 29% after the hydrothermal treatment. Fig. 1 shows the typical SEM image of NPPC powders. The average particle size of the NPPS powders was  $360 \pm 95 \text{ nm}$ , which was independent of synthesizing condition.

Arrhenius plots for the proton conductivity of 25 wt% PTFE-NPPC pellets are shown in Fig. 2. The maximum conductivities reached over  $8.6 \times 10^{-4} \text{ S cm}^{-1}$  at 80°C using NPPC-24 h-9 M. The proton conductivity of the NPPCs decreased with the increase in temperature. The TG/DTA-GC/MS measurements clarified that water content in the electrolytes decrease with increasing temperature below 130°C, which probably caused the depression of proton hopping and the diffusion of  $\text{H}_3\text{O}^+$  in the electrolytes. Sulfonic acid groups on NPPCs decomposed above 130°C to decrease the proton conductivity.

**Fig. 1.** SEM image of a NPPC synthesized by the hydrothermal method.

**Fig. 2.** Temperature dependence of the proton conductivity of NPPC under 10 mol%  $\text{H}_2\text{O-N}_2$  atmosphere. NPPC-24 h-9 M ( $\blacktriangle$ ), NPPC-7.5 h-18 M ( $\circ$ ) and NPPC-7.5 h-12 M ( $\blacksquare$ ).

# Characteristics of an intermediate-temperature fuel cell using proton conductive $\text{ZrO}_2\text{-1.6P}_2\text{O}_5$ -doped $\text{ZnO-2P}_2\text{O}_5$ hybrid electrolyte

## 1. Introduction

$\text{ZrO}_2\text{-1.6P}_2\text{O}_5$  has high proton conductivity ( $10^{-1.0}$  to  $10^{-1.5}$  S / cm) at a temperature range of 75°C to 250°C, but poor water resistance. In this study,  $\text{ZrO}_2\text{-1.6P}_2\text{O}_5$  doped  $\text{ZnO-2P}_2\text{O}_5$  hybrid electrolyte has been synthesized by heat treatment with the mixture of  $\text{ZrO}_2\text{-1.6P}_2\text{O}_5$  and  $\text{ZnO-2P}_2\text{O}_5$  for the development of a high proton conductive electrolyte with high water resistivity and low hydrogen gas permeability.

## 2. Experimental

$\text{ZrO}_2\text{-1.6P}_2\text{O}_5$  doped  $\text{ZnO-2P}_2\text{O}_5$  hybrid electrolyte was prepared as follows: A mixture of  $(\text{NH}_4)_2\text{HPO}_4$  (Junsei Chemical Co.) and  $\text{ZrCl}_2\text{O} \cdot 8\text{H}_2\text{O}$  (Wako Pure Chemical Industries) was heated at 500°C for 2 h under 10 mol%  $\text{H}_2\text{O}$  to synthesize  $\text{ZrO}_2\text{-1.6P}_2\text{O}_5$ . In order to synthesize  $\text{ZnO-2P}_2\text{O}_5$ , after a desired amount of Zn powder (Wako Pure Chemical Industries) and CaO (Kishida Chemical Co.) were dissolved in 86 wt%  $\text{H}_3\text{PO}_4$  (Kishida Chemical Co.) and the obtained solution was heat-treated at 900°C and quenched on a copper plate. The resultant  $\text{ZnO-2P}_2\text{O}_5$  glass was powdered by an agate mortar and was mixed with the desired amount of  $\text{ZrO}_2\text{-1.6P}_2\text{O}_5$ . The mixture heat-treated at a temperature range of 300°C to 900°C. Then, the sample was quenched on a copper plate to produce  $\text{ZrO}_2\text{-1.6P}_2\text{O}_5$  doped  $\text{ZnO-2P}_2\text{O}_5$  hybrid electrolytes (abbreviated as  $(\text{ZnO-2P}_2\text{O}_5\text{-0.3M CaO})\text{-}x$  wt% ( $\text{ZrO}_2\text{-1.6 P}_2\text{O}_5$ )).

## 3. Results and Discussion

The increase in the heat treatment temperature during the preparation process of the electrolytes caused the improvement of water resistance and the decrease in the proton conductivity of the electrolytes. The trade-off relationship between the water resistance and the proton conductivity became prominent with increasing ratio of  $\text{ZrO}_2\text{-1.6P}_2\text{O}_5$  in the hybrid electrolytes. Thus, the acceptable trade-off condition was heat treatment at 500°C and 30 wt%  $\text{ZrO}_2\text{-1.6P}_2\text{O}_5$  for the water resistance and the proton conductivity of the electrolytes. From the data of XRD measurements and SEM-EDX mappings, it was confirmed the core structure ( $\text{ZrP}_2\text{O}_7$ ) of  $\text{ZrO}_2\text{-1.6P}_2\text{O}_5$  was maintained and the  $\text{ZrO}_2\text{-1.6P}_2\text{O}_5$  was uniformly dispersed in the  $\text{ZnO-2P}_2\text{O}_5$ . The proton conductivity of the hybrid electrolyte showed almost the same level as that of  $\text{ZrO}_2\text{-1.6P}_2\text{O}_5$ . The water resistance and the hydrogen gas permeability of the hybrid electrolyte were 3 times and 1/80 times higher than those of  $\text{ZrO}_2\text{-1.6P}_2\text{O}_5$ , respectively.

Fig. 1 shows the single cell performance of an intermediate temperature fuel cell (ITFC) using the hybrid electrolyte. The OCV of the ITFC decreased with increasing operating temperature, suggesting the gas crossover through the electrolyte. The proton conductivity increased with an increase in the operating temperature, and the power density reached the maximum value of 5.2 mW at 275°C.

Ion-exchange membranes (IEMs) have been widely developed for the efficient separation processes of ionic substances such as electrodialysis, electrodeionization, diffusion dialysis, and water-splitting electrodialysis and so on. Recently, there has also been much attention towards IEMs for the applications in the energy generation and storage systems such as fuel cells (FCs) and redox flow batteries (RFBs). IEMs are one of the key components dominating the overall performances of the processes. Low ion transport resistance through membrane, excellent chemical and mechanical stability, high permselectivity, and low cross-over rate of undesirable components are required for the successful applications of the IEMs in the processes. The low cost of the membranes is also very important for the practical and commercial uses. In this work, we have successfully prepared high performance IEMs using engineering polymers, such as poly(2,6-dimethyl-1,4-phenylene oxide) (PPO) and polyetheretherketone (PEEK) as the based materials. In addition, the optimization of membrane design parameters has been systematically investigated using the membranes via various electrochemical analyses.

Ionic liquids (ILs) are promising materials for rechargeable batteries and capacitors because of their negligible vapor pressure, high thermal stability, and wide electrochemical potential window [1]. The most different feature of ILs compared with water and organic solvents is that ILs are composed of cations and anions only. Owing to these features, it was reported that the diffusion of metallocenes in ILs is not determined by the Stokes-Einstein equation [2]. In this study, we report the electrochemical redox behavior of cobaltocenium ( $\text{Cc}^+$ ) in imidazolium-based ILs to understand the effect of the alkyl chain length of cation on the activation energy for the diffusion and the Stokes radius of  $\text{Cc}^+$  in ILs.

10 mM  $\text{Cc}^+$  in  $[\text{C}_n\text{mim}][\text{TFSI}]$  ( $n = 2, 4, 6, 8, \text{ or } 10$ ) were prepared. The diffusion of  $\text{Cc}^+$  was investigated in each IL by using cyclic voltammetry (CV) and chronoamperometry (CA) at 20–70 ( $\pm 1$ ) °C. The Au(111) electrode was used as the working electrode. The potential values were calibrated to the ferrocene/ferrocenium ( $\text{Fc}/\text{Fc}^+$ ) reference electrode. The diffusion coefficients of  $\text{Cc}^+$  obtained from the Cottrell equation were utilized to estimate the activation energy for the diffusion by Arrhenius plots. The Stokes radius of  $\text{Cc}^+$  was estimated by the following equation [2]:

$$D = k_B T / (\theta \pi \eta \alpha), \quad \theta = 6 (1 + 2\eta/\beta\alpha) / (1 + 3\eta/\beta\alpha) \quad (\text{Eq. 1})$$

where  $D$  is the diffusion coefficient of  $\text{Cc}^+$ ,  $k_B$  is the Boltzmann constant,  $T$  is the temperature in Kelvin,  $\eta$  is the viscosity of an IL,  $\alpha$  is the Stokes radius of  $\text{Cc}^+$ ,  $\beta$  is the coefficient of sliding friction ( $0 \leq \beta \leq \infty$ ), and  $\theta$  is the Sutherland coefficient ( $4 \leq \theta \leq 6$ ).

Fig. 1 shows typical cyclic voltammograms of 10 mM  $\text{Cc}^+$  in  $[\text{C}_2\text{mim}][\text{TFSI}]$ . A reversible one-electron redox couple was observed. Similar voltammograms were obtained in the other  $[\text{C}_n\text{mim}][\text{TFSI}]$  ( $n = 4, 6, 8, \text{ or } 10$ ), but the peak currents for the reduction of  $\text{Cc}^+$  at various scan rates and temperatures were smaller when the alkyl chain length of  $[\text{C}_n\text{mim}]^+$  increased. Table 1 shows the activation energies for the diffusion and the Stokes radii of  $\text{Cc}^+$  in  $[\text{C}_n\text{mim}][\text{TFSI}]$ . The activation energy for the diffusion of  $\text{Cc}^+$  increased with the increase in the alkyl chain length of  $[\text{C}_n\text{mim}]^+$ , indicating that the viscosity of the medium affects the activation energy for the diffusion of  $\text{Cc}^+$ . On the other hand, the lowest Stokes radius of  $\text{Cc}^+$  was estimated in  $[\text{C}_4\text{mim}][\text{TFSI}]$  when the same Sutherland coefficient was used in each IL. This result indicates that  $\theta\alpha$  depends on  $[\text{C}_n\text{mim}]^+$  although  $\text{Cc}^+$  seems to attract  $[\text{TFSI}]^-$  by the electrostatic interaction. Our result suggests that Eq. 1 is more appropriate than the Stokes-Einstein equation for describing the diffusion of  $\text{Cc}^+$  in  $[\text{C}_n\text{mim}][\text{TFSI}]$ .

Fig. 1. CV profiles of 10 mM  $\text{Cc}^+$  in  $[\text{C}_2\text{mim}][\text{TFSI}]$  at 20 °C.

Table 1. The activation energies for the diffusion ( $E_a$ ) and the Stokes radii of  $\text{Cc}^+$  ( $\alpha$ ) in  $[\text{C}_n\text{mim}][\text{TFSI}]$ .

IL	$E_a$ [kJ mol <sup>-1</sup> ]	$\alpha$ [Å]	
		$\theta = 6$	$\theta = 4$
$[\text{C}_2\text{mim}][\text{TFSI}]$	28.2	3.1	4.6
$[\text{C}_4\text{mim}][\text{TFSI}]$	34.5	1.8	2.7
$[\text{C}_6\text{mim}][\text{TFSI}]$	32.0	1.9	2.8
$[\text{C}_8\text{mim}][\text{TFSI}]$	39.1	2.5	3.8
$[\text{C}_{10}\text{mim}][\text{TFSI}]$	45.7	3.1	4.6

Recently, electro-membrane processes using ion-exchange membranes have gained increased industrial importance. The electro-membrane processes are considered to be environment-friendly as well as energy efficient, since the generation of salt wastes can be minimized in these processes. Bipolar membranes in which the anion- and cation-exchangeable layers are adjoined together in series easily split water molecules into protons and hydroxyl ions under a reverse bias condition. It is expected that water-splitting electro dialysis using bipolar membrane can make zero-emission possible and be applied as a clean technology without the production of undesirable by-products. Very recently, an efficient electrochemical desalination process employing bipolar membranes with large ion-exchange area is being developed (so-called 'electro-adsorptive deionization'). In this process, ions dissolved in a feed solution can be removed through an ion-exchange mechanism under a strong electric field (a forward bias condition). The membranes can also be regenerated without the use of additional chemicals by the water-splitting reactions which occur at the bipolar junction of membranes (a reverse bias condition). The process performances, such as desalination efficiency and power consumption are largely dependent upon the properties of bipolar membranes. In this work, we have developed novel bipolar membranes containing iron oxide/hydroxide catalysts for efficient electrochemical water-splitting. Especially, new methods for the synthesis and immobilization of iron oxide/hydroxide catalysts have been developed to enhance the water-splitting efficiency of the membranes. In addition, the ion-exchange capacities of the bipolar membranes have been largely enlarged by embedding finely powdered ion-exchange resins.

Reverse electrodialysis (RED) is one of the promising processes for generating electricity from the salt concentration gradient between river and sea water. A RED stack contains alternately arranged anion and cation exchange membranes (AEMs and CEMs, respectively) which separate salt solutions of different concentrations. The power generation performance of RED significantly depends on the characteristics of ion exchange membranes (IEMs), which are selective for cations or anions. When the IEMs with different polarities are stacked alternately, with compartments for seawater or river water in between, the Donnan potentials over each membrane result in a voltage that can be used for electricity generation. The important membrane properties dominating the power generation in RED processes are ion-exchange capacity, water swelling degree, electrical resistance, permselectivity, membrane thickness, and surface morphology etc. In this work, we have successfully prepared high performance IEMs using engineering polymers, such as poly(2,6-dimethyl-1,4-phenylene oxide) (PPO) and polyetheretherketone (PEEK) as the based materials. In addition, the optimization of membrane design parameters has been systematically investigated using the membranes via various electrochemical analyses.

Biphasic systems with room temperature ionic liquid (RTIL)|water interfaces are crucial constituents of an increasing number of physicochemical systems including advanced materials [1,2]. Extraction and phase separation of RTIL and aqueous solution are intensively studied [3,4], whereas the application of RTIL–water systems in synthesis has been limited so far [5,6].

When the aqueous phase containing considerable amount of ionic species is in direct contact with a RTIL, the efficiency and pathway of interfacial processes involving charged reactants depends on the Galvani potential difference across the interface, controlled externally by means of a potentiostat or by the composition and concentration of ions in both phases [7-9]. Polarisation control of the liquid|liquid interface may provide favourable conditions for chemical reactions generating hydrogen or hydrogen peroxide [10]. It has been shown that H<sub>2</sub>O<sub>2</sub> can be obtained from dissolved dioxygen at the interface between water and an organic solvent immiscible with water (1,2-dichloroethane, trifluorotoluene) using a strong electron donor such as decamethylferrocene (DMFc) dissolved in the organic phase [11,12]. So far, these studies were restricted to interfaces formed by aqueous solutions of acids and salt solutions in nonaqueous polar solvents.

Here, we will demonstrate that by using the same methodology hydrogen peroxide can be generated at a RTIL|water interface:

The product was detected by, colorimetric substrate depletion, scanning electrochemical microscopy (SECM) and optical readout with fluorogenic substrate [13]. The experiments with carbon paste electrode with DMFc solution in hydrophobic ionic liquid demonstrated that electron donor can be regenerated electrochemically. This increases the flux of produced hydrogen peroxide as detected by SECM.

## 1. Introduction

Rotating ring-disk electrode (RRDE) is one of the most popular electrochemical tools, which enables quantitative analyses of electrode processes by controlling the mass transfer rate in the solution. However, the RRDE method, which needs a rotor-electrode system, glassy carbon-Pt ring electrode and an electrochemical cell equipped with a water jacket for temperature controls, becomes complex and of high cost. Moreover, the closed cell may cause the accumulation of interfering materials during the electrochemical reaction. We here propose a new handy electrochemical method named as "Ring disk flow cell (RDFC) method" that features advantages of both of the RRDE and the channel flow electrode. In this report, basic research has been performed including a comparison between the RRDE method and the new method, using a commercially available fuel cell catalyst.

## 2. Experimental

2.00 mg of 20 wt% Pt/XC72(E-TEK) was suspended in the 1 mL of 0.1 wt% Nafion<sup>®</sup>-methanol solution by a shaker at 1000 rpm for 1 h, then an aliquot of 7  $\mu$ L was cast on a glassy carbon (GC) disk electrode (5 mm $\phi$ ) of the RDFC, and was allowed to dry for 1 h at room temperature. Fig. 1 shows the scheme of a RDFC apparatus. The electrolyte solution was circulated from the reservoir to the electrochemical cell at desired flow rate controlled by a peristaltic tube pump (SMP-21S, EYELA). The electrochemical cell was equipped with the working electrode and a Nafion<sup>®</sup>115|EC-E20-10-07(1.0 mgPtcm<sup>-2</sup>)|H<sub>2</sub> membrane-electrode assembly, functioning as both the counter and the reference electrodes. Electrochemical measurements were carried out in 0.1 M HClO<sub>4</sub> with a multi potentiostat (PS-08, Toho Tech.) connected to a function generator (FG-02, Toho Tech.). Cathodic current of oxygen reduction reaction (ORR) was derived by subtracting the blank current measured under N<sub>2</sub> from the current under O<sub>2</sub>.

## 3. Results and discussion

Fig. 2 shows the ORR polarization curves on GC disk electrodes supporting 20 wt% Pt/XC72 (E-TEK) with 0.1  $\mu$ M Nafion<sup>®</sup>, measured by RRDF and RRDE methods. The less steep current decrease towards the diffusion limiting current observed in the RDFC as compared with the RRDE, indicates the IR drop due to the contact resistance of the working electrode. To overcome this problem, the reduction of contact resistance in the RDFC is now attempted in several ways.

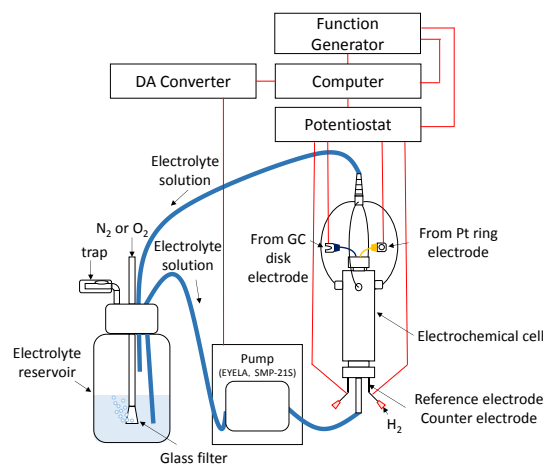

Fig. 1. Scheme of a ring-disk flow cell apparatus.

Fig. 2. Polarization curves for oxygen reduction on GC|20 wt% Pt/C(E-Tek) with 0.1  $\mu$ M Nafion<sup>®</sup> during positive going scan in 0.1 M HClO<sub>4</sub> under 1 atm O<sub>2</sub> at 20°C. — : ring-disk flow electrode (8 mL min<sup>-1</sup>); .....: RRDE (600 rpm).

# Effects of constant on-off current pulse on the properties of $\text{Cu}_2\text{O}$ films fabricated by electrochemical deposition method

Leo Chau-Kuang Liao\*, Po-Chin Tseng, and Jia-Lin Jhan

Department of Chemical Engineering and Materials Science, Yuan Ze University, Chung-Li 32003, Taoyang city, Taiwan

\*e-mail: lckliau@saturn.yzu.edu.tw

Cuprous oxide ( $\text{Cu}_2\text{O}$ ) is a direct band-gap semiconductor material which is abundant and nontoxic and considered in the development and application of the recent optoelectronic technology.<sup>1</sup> Optoelectronic devices, such as  $\text{Cu}_2\text{O}$ -based solar cells,<sup>2,3</sup> were designed and produced to take advantages of the unique properties of  $\text{Cu}_2\text{O}$ . However, the properties of  $\text{Cu}_2\text{O}$  films were greatly affected by the fabrication methods. In this study, the effects of constant on-off current pulse processes on the properties of  $\text{Cu}_2\text{O}$  films fabricated using electrochemical deposition (ECD) were investigated. The  $\text{Cu}_2\text{O}$  films were prepared using a ECD solution, mixed of Copper (II) acetate ( $\text{Cu}(\text{OOCCH}_3)_2 \cdot \text{H}_2\text{O}$ ) with acetic acid to adjust pH = 4.9 at 70 °C. The ECD process was carried out under the control of different on-off periods of the current pulse. Results showed that the morphologies of the  $\text{Cu}_2\text{O}$  particles were greatly affected by the ECD parameters, such as voltage and current setup. The particle shapes change from dendritic (Figure 1(a)), cubic (Figure 1(b)), to faceted (Figure 1(c)), for the operating conditions setup at constant voltage, constant current, and constant on-off current pulse approaches, respectively. The particle sizes of the respective samples were 2.0  $\mu\text{m}$ , 5.0  $\mu\text{m}$ , and 0.35  $\mu\text{m}$  evaluated from Figures 1(a) – 1(c). Additionally, the particle sizes of the ECD samples can also be varied by different on-off periods of current pulse according to the SEM image data. The crystalline sizes of all these samples were similar and analyzed to be 47 nm from the analysis of the XRD spectral data. The electronic properties of the films were determined using the Mott-Schottky analysis and current-voltage (I-V) tests. The properties of the  $\text{Cu}_2\text{O}$  films using constant current pulse in different on-off periods were also discussed in this work.

Figure 1 SEM morphologies of the  $\text{Cu}_2\text{O}$  particles using ECD processing setup for (a) constant voltage, (b) constant current, and (c) constant on-off current pulse methods.

Room-temperature ionic liquids (RTILs) have been regarded as potential electrolytes for various electrochemical systems. From this point of view, RTILs based on nitrogen-based cations have been considerably reported in recent years; however, RTILs based on phosphonium cations have been rarely investigated. On the other hand, interests in a tetracyanoborate ( $\text{B}(\text{CN})_4^-$ , TCB) anion based ILs have been increasing for their electrochemical application due to the fact that the TCB-based ILs exhibited remarkably high transport property [1]. In this work, we report the preparation and physicochemical properties of novel ILs based on quaternary phosphonium cations [2] together with the TCB anion (Fig. 1).

Fig. 1 Ionic components of phosphonium ILs in this work.

The preparation of the phosphonium ILs was performed by aqueous ion exchange reactions of precursor phosphonium halides with sodium tetracyanoborate ( $\text{Na-TCB}$ ). Residual metal and halide ions in the crude ILs were removed by a silica gel column. The physicochemical and electrochemical properties such as conductivity, viscosity, density, melting point, thermal decomposition temperature and electrochemical window were measured under argon atmosphere.

The combination of the asymmetric phosphonium cations with TCB anion successfully gave liquids at ambient temperature.

As shown in Fig. 2, it was found that phosphonium ILs based on TCB anion showed relatively high conductivity when compared to the corresponding ammonium IL, which were similar to those observed in bis(fluorosulfonyl)amide (FSA)-based and bis(trifluoromethylsulfonyl)amide (TFSA)-based phosphonium ILs. This result might be due to the charge distribution on the TCB anion.

Fig. 3 suggests that the thermal decomposition temperature of TCB-based phosphonium ILs were more than approximately 400°C, indicating their higher thermal stability than those of the other ILs.

Nanopatterning of AuNPs on ITO electrode is reported in this abstract. The nanospheres lithography (NSL) encompassed the deposition of monolayered Polystyrene (PS) via drop casting protocol onto the ITO substrate that further acted as the mask for the gold nanoparticles (AuNPs) assembly. Results show that AuNPs spin coating allowed AuNPs to follow the contour and stick around the PS nanospheres. The final products after etching of PS generated a highly-ordered AuNPs array on ITO substrate. This hexagonal AuNPs array on ITO electrode provided greater surface area and successfully enhanced the peak current of electrochemical measurement and was used in the detection of DNA hybridization. As compared with the non-templated AuNPs structure, the patterned AuNPs array on ITO electrode contributed an optimum sensitivity improvement in the DNA hybridization detection by 20%. The high specificity of this distinguished structure was also achieved in the hybridization measurement of multi-analyte pathogens. Findings indicate that PS nanosphere lithography with its inexpensive and simple fabrication has effectively generated uniform patterned AuNPs array on ITO which provides greater surface area to optimize electrochemical performance of the DNA biosensor.

# Simultaneous Determination of Ascorbic acid, Norepinephrine and Uric acid by Differential Pulse Voltammetry on a Disposable Pencil Graphite Electrode in the Pharmaceutical Formulations and Human Urine Samples

Abdulkadir Levent, Günay Önal

Batman University, Health Services Vocational College, 72100 Batman, Turkey

E-mail: [leventkadir@hotmail.com](mailto:leventkadir@hotmail.com)

Norepinephrine (NE) is a very important neurotransmitter in the mammalian central nervous system and mechanical pressure to excite sensory nerve endings in the skin, chemical neurotransmitters to transmit signals from one neuron to the next in the brain, and electrical current to transmit signals between successive muscle cells in the heart and intestine [1]. Ascorbic acid (AA) and Uric acid(UA) are important analytes that present in many biological fluids. A large number of papers in the literature involve the use of modified electrodes [2,3].

In this study, the electrochemical behaviors of AA, NE and UA on the pencil graphite electrode (PGE) were investigated by cyclic voltammetry (CV) and differantial pulse voltammetry (DPV) at different supporting solutions (acetate, phosphate and Britton-Robinson). By simultaneously changing the concentrations of these three molecules, their electrochemical oxidation peaks appeared at +0.16, 0.41 and 0.54 V, respectively (Figure 1). The peak currents were found to vary linearly with their concentrations in the range of 250-850 nM, 40-160 nM and 60-180 nM for AA, NE and UA, respectively. The proposed electrochemical method was successfully applied for quantification AA and NE individually in commercial pharmaceutical formulations, and AA and NE plus UA in spiked human urine samples. The prepared electrode showed several advantages, such as a modified electrode method, high sensitivity and low detection limits.

**Figure 1.** DP voltammograms of AA, NE and UA in BR buffer at pH 4.0 at PGE, DPV parameters: Step Potential, 1 mV; Modulation amplitude, 40 mV; Modulation Time, 0.03 s, Interval Time 0.4 s.

# Synthesis and Electrochemical FTIR Study of Nanoporous Palladium-Based Bimetallic Catalysts

Aicheng Chen<sup>\*</sup>, Suresh Konda, Cassandra Ostrom, Brian Adams, Robert Asmussen  
*Department of Chemistry, Lakehead University*  
955 Oliver Road, Thunder Bay, Ontario P7B 5E1, Canada  
achen@lakeheadu.ca

Palladium is well known for its high affinity to hydrogen, which enables the use of palladium nanomaterials as a primary catalyst over a wide variety of applications [1-3]. In view of the inherent limitations of current portable technology energy sources, the implementation of micro fuel cells is becoming increasingly appealing. This has generated a great interest in the development of direct formic acid micro fuel cells. In this presentation, we report on the synthesis and comparative study of nanoporous palladium-based bimetallic catalysts for formic acid oxidation.

Five Pd-based nanoporous catalysts (Pd, PdCd, PdPb, PdIr, and PdPt) with controlled compositions were synthesized and examined for their electrocatalytic activity in the oxidation of formic acid. For each of the bimetallic catalysts with 10 at.% additive metal, the hydrothermal synthesis method resulted in the formation of alloys between Pd and the additional metal, as determined by XRD. Several electrochemical techniques, including linear sweep voltammetry and chronoamperometry, were utilized to compare the activity of the catalysts toward the oxidation of formic acid. The chronoamperometric measurements showed that the current responses at 0.10 V attained the highest values within 0.8 s, which were relatively close for all five of the nanoporous Pd-M electrodes, indicating that the initial electrode performance toward formic acid oxidation was independent of the alloying materials (Cd, Ir, Pd, and Pt). In contrast, the ratio of the steady state current measured at 500 s gave rise to the following order: PdIr (1.97) < PdPt (2.44) < PdCd (3.91) < Pd (4.62) < PdPb (5.26), showing that the second incorporated metal strongly affected the stability of the Pd-based electrocatalysts. With the aid of in situ ATR-FTIR spectroscopy, the mechanisms of formic acid oxidation were investigated for the Pd-based nanoporous catalysts. Formic acid oxidation on the nanoporous Pd, PdCd, and PdPb catalysts proceeded predominantly through the direct mechanism; whereas the indirect mechanism was observed for the PdIr and PdPt catalysts. The incorporation of even small amounts of Pt and Ir was found to inhibit the oxidation of formic acid, with the generation of large volumes of CO, which caused a rapid decay in catalytic activity. In contrast, the addition of inexpensive Pb still promoted the direct mechanism, which might facilitate further increase of the activity and decrease in the cost of Pd-based catalysts.

Submit to the Symposium 18: General Session

Vapor phase inhibitor is needed to control the top of line corrosion (TLC) in wet gas pipeline. The corrosion inhibition of 2-(1-methyl-nonyl)-quinoline in CO<sub>2</sub>-saturated standard NACE solution was studied by electrochemical measurements, SEVT, molecular dynamics method and surface analysis techniques. It is found that, the adsorption of quinoline inhibitor on X80 steel surface obeys Langmuir adsorption isotherm and has a characteristic of parallel adsorption. The inhibitor film prevents the corrosion media from reacting with the steel. The inhibition efficiency increases with the temperature from 30°C to 50°C and pH from 4.15 to 5.76. The inhibition efficiency is 97.25% when the concentration of quinoline is 0.0282mol/l. The X80 steel surface was divided into two parts, in which the part from x=0 μm to 3500μm was covered with inhibitor film and the other part was without inhibitor. The SEVT results show the obvious difference of current densities in the absence and presence of quinoline. The part with quinoline was cathode region and the average current density of the other part is about 2 times than the cathode region. The SEM pictures show that X80 steel immersed with quinoline is covered with inhibitor film. The pitting corrosion exists when the X80 steel is without inhibitor.

ENGY0008@e.ntu.edu.sg

Beyond MoS<sub>2</sub> as the first transition metal dichalcogenide (TMD) to gain recognition as an efficient catalyst for the hydrogen evolution reaction (HER), interest in other TMD nanomaterials is also beginning to proliferate. Various electrochemical applications have been proposed, ranging from catalysis to supercapacitors and solar cells. Despite this rise, current understanding of their intrinsic electrochemical characteristics is especially lacking with few prior studies conducted [1,2]. We examine the inherent electroactivity of various chemically exfoliated TMDs (MoSe<sub>2</sub>, WS<sub>2</sub>, WSe<sub>2</sub>) and discuss their implications for sensing, catalysis of the hydrogen evolution, and oxygen reduction reactions (ORR) [3]. TMDs studied are found to possess distinctive inherent electroactivity. Together with their catalytic effects for the HER these strongly depend on the chemical exfoliation route and metal-to-chalcogen composition particularly in MoSe<sub>2</sub>. Inherent MoSe<sub>2</sub> electrochemistry shows the most variation depending on the exfoliation extent, but is also the most efficient HER catalyst with a low overpotential of -0.36 V vs RHE (at 10 mA cm<sup>-2</sup> current density) and reasonably low Tafel slope of ~65 mV/dec after BuLi exfoliation. It also demonstrates an improved heterogeneous electron transfer rate towards the ferro/ferricyanide redox couple, as compared to conventional glassy carbon electrodes. Knowledge of TMD electrochemistry is essential for the rational development of future applications since inherent TMD activity may potentially limit certain usages.

A flexible all-solid-state electrochromic device (ECD), assembled with a polymeric crystal composite electrolyte and tungsten oxide/nickel oxide (WO<sub>3</sub>/NiO) complementary system, is demonstrated in this study. The polymeric crystal composite electrolyte, which is composed of a UV-cured ethoxylated trimethylolpropane triacrylate (ETPTA), succinonitrile (SN) and 2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO), is used as the electrochromic material and electrolyte in the flexible all-solid-state ECD. The optimal composition ration of this composite is at the weight ratio of 20/80 for ETPTA/SN with 1 M LiBF<sub>4</sub>. For the cathodic electrochromic electrode, a flexible polyethylene terephthalate (PET) is used as the substrate, and indium–tin–oxide (ITO) and WO<sub>3</sub> are deposited sequentially on the PET by sputtering. A NiO/ITO/PET electrode prepared by sputtering is used as the anodic coloring electrode. The thickness of ITO, WO<sub>3</sub> and NiO film is 110, 70 and 60 nm, respectively. This flexible all-solid-state ECD fabricated with the polymeric crystal composite electrolyte shows an optical contrast of *ca.* 33.7% at 550 nm. The optical transmittance of the ECD at 550 nm can be reversibly modulated from 59.7% (bleached) to 26.0% (darkened), by applying potentials of 1 and -2.5 V, respectively.

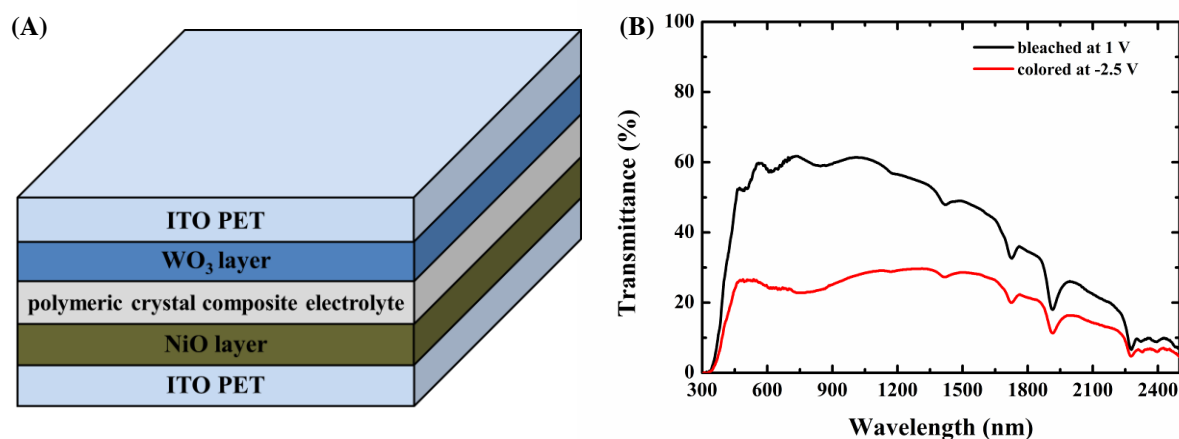

Figure 1 (A) The Schematic diagram of the flexible all-solid-state ECD. (B) The optical transmittance spectra of the ECD recorded under different applied potentials at -2.5 and 1 V.

# Simultaneous Determination of Ascorbic Acid, Epinephrine and Uric Acid by Differential Pulse Voltammetry on a Disposable Pencil Graphite Electrode

E-mail: [leventkadir@hotmail.com](mailto:leventkadir@hotmail.com)

Ascorbic acid (AA), epinephrine (EP), and uric acid (UA) are important human body compounds that play determining role in metabolism; hence, monitoring their concentration in biologic fluids such as blood and urine may prevent and control many diseases. Since these compounds are all electroactive, it is possible to develop voltammetric analysis for their determination. However, they are oxidized at similar oxidation potentials at most solid electrodes which results in rather poor selectivity. So the ability to selectively detect AA, EP, and UA has been a matter of great interest to bioelectrochemists, electroanalytical chemists and neuroscientists. A large number of papers in the literature involve the use of modified electrodes [1-3]. The present study is intended to investigate the electrochemical behaviors of AA, EP and UA on single-use disposable pencil graphite electrode (PGE) by cyclic voltammetry (CV) and differential pulse voltammetry (DPV).

After optimization of analytical conditions employing this electrode, well-defined oxidation peaks for AA, EP, and UA were obtained at pH 4.0 in Britton-Robinson buffer solution (0.1 M) using DPV. By simultaneously changing the concentrations of these three molecules, their electrochemical oxidation peaks appeared at +0.17, 0.37 and 0.51 V, respectively (Figure 1). The peak currents were found to vary linearly with their concentrations in the range of 300-900 nM, 50-150 nM and 75-195 nM for AA, EP and UA, respectively. The proposed electrochemical method was successfully applied for quantification AA and EP individually in commercial pharmaceutical formulations, and AA and EP plus UA in spiked human urine samples.

The remarkable analytical sensitivity of the PGE, together with its simplicity and being low cost which enables its use without applying any series of chemical modification steps for electrode preparation, makes this electrode very promising for determination of AA, EP and UA in their mixture.

Figure 1. DP voltammograms of AA, EP and UA (from left to right) in Britton-Robinson buffer, pH 4.0 at PGE.

Many people live under oxidative stress, defined as the imbalance between reactive oxygen and nitrogen species and antioxidant defence. To decrease the risk of developing pathology from oxidative stress, extensive attention has been devoted to the intake of dietary antioxidants such as polyphenolic compounds, vitamins, and carotenoids from natural products. Thus, many people are interested in knowing the antioxidant capacities of foods and beverages. Many methods have been developed for evaluating the antioxidant capacity of foods and beverages; these methods are mostly based on spectrophotometric measurements such as UV-Vis spectrophotometry and fluorescence spectrophotometry. Such spectrophotometric evaluation methods of antioxidant capacity require skills to obtain correct values with high precision, and spectrophotometers are very expensive, implying that it is difficult for many people to evaluate antioxidant capacity for foods and beverages by themselves.

Polyoxometalates (POMs), which consist of molybdenum, tungsten and oxygen in the framework, and phosphorus and silicon at the center of POMs (Fig. 1), exhibit excellent electrochemical properties rather than general metal-complexes.

In this study, a new electrochemical method was developed for evaluating antioxidant capacity based on the redox properties of POMs. Antioxidant capacity was estimated from an equilibrium potential shift of POMs reduced partially by antioxidants (Fig. 2). The antioxidant capacities of gallic acid, ellagic acid, catechin, quercetin, morin, *trans*-ferulic acid, sesamol,  $\alpha$ -tocopherol,  $\delta$ -tocopherol and L-ascorbic acid, which are major antioxidants contained in foods and beverages, were potentiometrically evaluated under the optimised conditions. The observed potential shifts ( $\Delta E$ ) were compared with the spectrophotometrically evaluated antioxidant capacities. In addition, the antioxidant capacities of some types of beverages such as tea, juice and wine, were evaluated.

In recent years, lithium-rich  $\text{Li}_2\text{MO}_3$  compounds (M: transition metals) such as  $\text{Li}_2\text{MnO}_3$  have been extensively investigated because they or their solid solutions with  $\text{LiMO}_2$  (widely used in current as cathode materials) show higher specific capacities than the  $\text{LiMO}_2$  compounds alone. Therefore, many structural examinations of these  $\text{Li}_2\text{MO}_3$  compounds have hitherto been performed. Of these  $\text{Li}_2\text{MO}_3$  compounds, the structure of  $\text{Li}_2\text{MnO}_3$  is reported to have a monoclinic structure ( $C2/m$ ), in which Li, transition metal (TM), and O layers are ABC-stacked the same as in the  $\text{LMO}_2$  crystals (Strobel model [1]). However, the TM-layers in the former crystals are occupied also by lithium atoms ( $2b$  site) together with Mn atoms ( $4g$  site) unlike in the latter crystals [Fig. 1(a)]. It has been believed that this  $\text{Li}_2\text{MnO}_3$  structure is maintained from low temperatures just after the solid-phase reaction for its compound synthesis to high temperatures near the melting point. Our present x-ray powder diffraction analysis of  $\text{Li}_2\text{MnO}_3$  materials synthesised at various temperatures, however, revealed that the  $2b$  site is occupied mainly not by lithium atoms, but by manganese atoms, and that the  $4g$  site is occupied by approximately 50% lithium and 50% manganese atoms [see Fig. 1(b)]. This Li and Mn atomic configuration at the TM layer can be regarded as having the opposite order to that of the Stroble model. This Li/Mn arrangement found in low-temperature calcined materials, however, changed as a function of the synthesis temperature; and gradually approached that of the Strobel model as the heat treatment temperature increased. This newly found structure was also confirmed by neutron and synchrotron joint analyses; in addition, we further performed the HAADF-STEM direct observations on single crystallites in low-temperature-calcined  $\text{Li}_2\text{MnO}_3$  and ensured the presence of the new structure in them. Ionic conduction of Li atoms in solid substances is considered to be caused by their hopping from one Li atomic site to other neighboring Li sites. In the atomic configuration of the Strobel model, i.e. perfectly ordered model,  $\text{Mn}^{4+}$  ions are always located close to the hopping paths and inhibit the  $\text{Li}^+$  ion conduction without exception. However, in the newly found crystal structure of  $\text{Li}_2\text{MnO}_3$  with significant cation mixing in the TM layers, the formation of three-dimensional chains with only low Coulomb potential barriers becomes possible by random replacement of the obstacle Mn ions with the favorable Li ions, which can shape smooth lithium ion diffusion (percolation) paths in the crystal. Here, note that the Coulomb potential barrier of the favorable  $\text{Li}^+$  ion is far lower than that of the obstacle  $\text{Mn}^{4+}$  ion [2]. This work received the support of the Research and Development Innovative for Scientific Innovation of New Generation Battery (RISING) project of the New Energy and Industrial Technology Development Organization (NEDO), Japan.

Quinones, which are naturally occurring redox active organic compounds, have been proposed as cathode materials in lithium ion batteries for their high theoretical specific capacities and more environmentally friendly manufacturing compared to conventional inorganic cathode materials. However, many of them suffer from poor kinetics as well as capacity loss due to dissolution.<sup>1</sup> In our work, by attaching quinones as pendant moieties onto conducting polymers, e.g. polypyrroles, we have composed conducting redox polymers, which are expected to decrease problems with resistance and dissolution while retaining capacity and cyclability.<sup>2</sup> A series of monomeric compounds incorporating pyrrole and quinone units were synthesized and polymerized electrochemically. The resulting polymers were studied by in-situ spectro-electrochemical techniques as well as by EQCM to elucidate the redox chemistry of the quinone units as well as the kinetics of polymer redox performance.

Solid polymer electrolytes (SPEs) have long been the subject of intense research because of their potential electrochemical applications in solid-state rechargeable lithium batteries, dye-sensitized solar cells, chemical sensors, data storage and electrochromic devices [1-3]. In the present study, a new type of comb-branched organic-inorganic hybrid electrolyte based on the reaction of polymethylhydrosiloxane, allytriethoxysilane, poly(propylene glycol)-*block*-poly(ethylene glycol)-*block*-poly(propylene glycol) bis(2-aminopropyl ether), and 3-(glycidyloxypropyl)trimethoxysilane has been prepared by varying the LiClO<sub>4</sub> concentration. <sup>13</sup>C CPMAS NMR and Fourier transform infrared spectroscopy (FTIR) results provide the information about the successful synthesis of the hybrid membrane. The hybrid electrolyte exhibits semi-crystalline to amorphous structure with the increase in salt concentration. A maximum ionic conductivity of  $6.2 \times 10^{-5} \text{ S cm}^{-1}$  is obtained at 30 °C for the solid hybrid electrolyte with a [O]/[Li] ratio of 16. The good value of electrochemical stability window (~ 4V) makes the hybrid electrolyte promising for electrochromic devices and sensors applications.

Temperature dependence ionic conductivity of organic-inorganic hybrid electrolyte with different [O]/[Li] ratios, X.

Polymer electrolyte is one of the promising research areas that attracted ever-increasing interests due to its potential applications in electrochemical devices, such as rechargeable lithium-ion batteries, dye-sensitized solar cells, electrochromic devices, etc. [1–3]. In this study, a new type of highly conductive organic–inorganic hybrid polymer electrolytes has been synthesized based on polymerization of poly(propylene glycol)-block-poly(ethylene glycol)-block-poly(propylene glycol) bis(2-aminopropyl ether) (ED2003), 2,4,6-trichloro-1,3,5-triazine (cyanuric chloride, CC) and alkoxysilane precursor (3-isocyanatopropyl)triethoxysilane (ICPTES), followed by doping various amounts of  $\text{LiClO}_4$  salt. The  $^{13}\text{C}$  and  $^{29}\text{Si}$  solid-state NMR and Fourier transform infrared spectroscopy results reveal the successful synthesis of the organic–inorganic hybrid structure. The solid hybrid electrolyte exhibits a maximum ionic conductivity of  $1.1 \times 10^{-4} \text{ S cm}^{-1}$  at  $30^\circ\text{C}$  for the  $[\text{O}]/[\text{Li}]$  ratio of 32. The hybrid electrolyte possesses a good electrochemical stability window of 4.0 V. The prototype electrochromic device with such a solid hybrid electrolyte demonstrates exceptionally high coloration efficiency value of  $732 \text{ cm}^2 \text{ C}^{-1}$ . The present organic–inorganic hybrid electrolytes hold promise for applications in electrochromic devices and lithium ion batteries.

Temperature dependence ionic conductivity of organic-inorganic hybrid electrolyte with different  $[\text{O}]/[\text{Li}]$  ratios, X.

WONG0804@e.ntu.edu.sg

The synthesis of graphene materials is typically carried out by oxidizing graphite to graphite oxide, followed by a reduction process. Numerous methods exist for both the oxidation and reduction steps, which causes unpredictable contamination from metallic impurities into the final material. These impurities are known to have considerable impact on the properties of graphene materials. We synthesized several reduced graphene oxides from extremely pure nuclear graphite using several popular oxidation and reduction methods, and tracked the concentrations of metallic impurities at each stage of synthesis. We demonstrate that different combinations of oxidation and reduction introduce varying types as well as amounts of metallic elements into the graphene materials, and their origin can be traced to impurities within the chemical reagents used during synthesis. These metallic impurities are able to alter the graphene materials' electrochemical properties significantly, and have wide-reaching implications on the potential applications of graphene materials.

# Molybdenum Disulfide (MoS<sub>2</sub>) Nanoflakes as Inherently Electroactive Labels for DNA Hybridization Detection

Adeline Huiling Loo, Alessandra Bonanni, Adriano Ambrosi and Martin Pumera

*Division of Chemistry & Biological Chemistry, School of Physical and Mathematical Sciences, Nanyang Technological University  
21 Nanyang Link, Singapore 637371, Singapore  
S120022@e.ntu.edu.sg*

The detection of specific DNA sequences plays a critical role in the areas of medical diagnostics, environmental monitoring, drug discovery and food safety. This has therefore become a strong driving force behind the ever-increasing demand for simple, cost-effective, highly sensitive and selective DNA biosensors. In this study, we report for the first time, a novel approach for the utilization of molybdenum disulfide nanoflakes, a member of the transition metal dichalcogenides family, in the detection of DNA hybridization. Herein, molybdenum disulfide nanoflakes serve as inherently electroactive labels, with the inherent oxidation peak exploited as the analytical signal. The principle of detection is based on the differential affinity of molybdenum disulfide nanoflakes towards single-stranded DNA and double-stranded DNA. The employment of transition metal dichalcogenides nanomaterials for sensing and biosensing purposes represents an upcoming research area which holds great promise. Hence, our findings are anticipated to have significant contributions towards the fabrication of future DNA biosensors.

# **Fate of silver nanoparticles in natural waters; integrative use of conventional and electrochemical analytical techniques**

Wei Zhe Teo, Martin Pumera

*Division of Chemistry & Biological Chemistry, School of Physical and Mathematical Sciences,  
Nanyang Technological University  
21 Nanyang Link, Singapore 637371  
TEOW0051@e.ntu.edu.sg*

The rapid emergence of commercially available products containing silver nanoparticles (AgNPs) in recent years is worrying, as the widespread use of these items could lead to hazardous silver pollution to our environment waters. When released into the environment, AgNPs' toxicity and transport in water is ultimately dependent on its transformation. Therefore, the study on AgNPs' transformation in different aqueous environments is important in predicting the damage that will be incurred by the accumulation of AgNPs in natural waters. In this paper, we investigated the AgNPs speciation in three types of aqueous media (ultrapure water, lake water and seawater) after one week of dispersion using analytical techniques such as inductively coupled plasma mass spectrometry (ICP-MS), and X-ray photoelectron spectroscopy (XPS). The amount of Ag ions measured in the AgNPs–seawater suspension was found to be one order of magnitude higher than the amount measured in the AgNPs–ultrapure water suspension, hence indicating that the extent of transformation of Ag<sup>0</sup> to ionic Ag in AgNPs is very different. Furthermore, the data acquired from XPS analysis showed that the metallic state of silver prevailed after dispersion in all three types of water, suggesting that the AgNPs did not undergo any reactions that resulted in the formation of silver containing compounds. Cyclic voltammetry (CV) was also performed for the study of the transformation of AgNPs. The trend gathered from the magnitudes of the AgNPs oxidation peak (0.52  $\mu$ A, 12.2  $\mu$ A and 49.2  $\mu$ A for AgNPs–seawater, AgNPs–lake water and AgNPs–ultrapure water suspensions respectively) exhibited a positive relationship with that attained from the ICP-MS and XPS results, demonstrating the likelihood of employing this technique as a simple and rapid alternative in future work in this field.

# A study on Supercritical Electrolytic Polishing Process for Stainless steel substrates

## Abstract

The polishing technique is an important surface treatment method used in both conventional and electronic industry. Traditionally, there are three main skills included (1) mechanic polishing (2) electrolytic polishing (3) chemical polishing. However, all of them could not deal with complex parts with higher aspect ratio and serious environmental problem with labor cost. In this work, we have explored a new polishing method which applies principles of electro-chemistry and electro-physics to treat the surface of stainless substrate under the supercritical carbon dioxide fluid. It used to get rid of oxides on it and to increase its smoothness as well as brightness. The various kinds of golf head were selected as the investigated system. The roughness of sample can be upgraded to nano-metered size ( $\sim 200\text{nm}$ ) and the it's brightness of mirror also be obtained (reflectivity  $> 95\%$ ). It is highlighted that the new supercritical polishing method is a green process without polluting environments and it is suitable to complex work pieces and simple operation with high efficiency.

**Keywords :** polishing, gold head, brightness, roughness

The Austenite type of stainless were the investigated samples included SUS 303, 304 and 316. The applied electrical field was controlled at 280 volts and operating temperature setted at  $75^\circ\text{C}$ . The dependence of process time on roughness and brightness of substrates were shown in Figure 1 and Figure 2, respectively. The results indicate that the optimal roughness and brightness were achieved after 10 minutes. Smooth finish of substrates can be increased 2-3 grades after polishing and the roughness,  $R_a$ , less than  $0.1\mu\text{m}$  as well as brightness,  $r$ , larger than 95%. The data also show that the polishing effect have the following order: SUS 316 > SUS 304 > SUS 303.

Figure 1 Polishing effect on roughness .

Figure 2 Polishing effect on brightness.

# Quantifying Surface Diffusion by Nanoelectrode

Wei Wang, Fang-Fang Wang, Jie Zhang, Bao-Fa Su, Dong-Ping Zhan\*, Zhong-Qun Tian

The mobility of adsorptive atoms and molecules on catalyst surface is one of the most fundamental issues in solid surface science. It plays a pivotal role in myriad physiochemical processes, especially in thin-film deposition and heterogeneous catalysis. To quantify the surface mobility will aid in deeply understanding the mechanism of these processes. Therefore, numerous methods have been developed for measuring surface diffusion coefficient, and many systematic investigations have been performed on solid surfaces in vacuum or atmospheric environment.

However, studying surface mobility on solid surface in liquid environment, especially in electrochemical system, still faces challenges both in experiment and theory. The reason mainly lies in that most of the techniques adopted for surface diffusion traditionally don't work at the solid/liquid interfaces. Moreover, the coadsorption of the water molecules or electrolyte ions and the presence of strong electric fields make it extremely complicated at the electrochemical interface. Nevertheless, information on the transport and interaction of atoms or molecules on electrode surfaces is badly needed for gaining insights into many electrochemical interface processes, such as electrodeposition and electrocatalysis. These processes are directly related to electrochemical energy conversion, metal electrode processes as well as other electrocatalytic domains.

The surface diffusion of hydrogen adatoms on Pt nanoelectrodes along Pt/SiO<sub>2</sub> boundary in acidic solution has been observed directly in our previous work.<sup>1</sup> Here, we present a method based on Fick's second law to further prove the existence of surface diffusion of adsorbates and quantitatively separate the Faraday adsorption area and surface diffusion area on Au or Pt nanoelectrodes. The surface diffusion coefficients of the oxygen-containing adsorbates on Au or Pt surface were obtained.

# A Novel Photoelectrocatalytic Approach for Regenerating NaOH by a BiOCl/bipolar Membrane Sandwich Structure

Zhenhai Liang\*, Xian Liu, Xuan Jian, Yang huimin  
*College of Chemistry and Chemical Engineering, Taiyuan University of Technology*

A novel photoelectrocatalytic approach for regenerating NaOH through a BiOCl/bipolar membrane (BiOCl/BPM) sandwich structure with photoelectro-synergistic catalysis is proposed in this study. This distinctive BiOCl/BPM sandwich structure presents four advantages. (1)The high-electric field at the interlayer contributes in separating photo-induced electron-hole pairs, thereby improving water splitting into protons and hydroxide ions. (2) In a high-electric field,  $H^+$  and  $OH^-$  are generated at the interlayer of the BiOCl/BPM, and migrate into the cathode and the central chambers, respectively, thereby decreasing the reverse reaction of the as-formed  $H^+$  and  $OH^-$  to form  $H_2O$  again. (3)The membrane impedance of the BiOCl/BPM decreased under the sunlight irradiation, which reduced energy consumption. (4) This technique not only makes full use of the recyclable bases, but also limits the usage of acids.

The BiOCl/BPM was prepared using a paste method. The anode chamber was fed with the spent caustic (200 mL), the cathode chamber was fed with 0.3mol/L  $Na_2SO_4$  (200 mL) as the supporting electrolyte solution, and the central chamber was fed with 0.1mol/L NaOH solution (200 mL). The anode was a Pt electrode, and the cathode was a Pd electrode. A 350W xenon lamp with 350–760 nm filters as simulative sunshine.

The principle is shown in Scheme 1. The BiOCl/BPM sandwich structure with consists of an anion-exchange membrane layer (AM), a cation-exchange membrane layer (CM) and a BiOCl catalyst layer (i.e. interlayer). The interlayer has a nano-size thickness ( $10^{-7}$  m to  $10^{-9}$  m); thus, the electric field intensity at the interlayer reaches from  $10^7$  V  $m^{-1}$  to  $10^9$  V  $m^{-1}$  when 1 V is applied.  $H^+$  and  $OH^-$  are generated at the interlayer of the BPM using a high-electrical field and solar irradiation. Sodium ion ( $Na^+$ ) in the spent caustic migrates through the CM to the base compartment, where it combines with  $OH^-$  produced by the BiOCl/BPM to generate sodium hydroxide (NaOH).

# Synthesis and Electrochemical Performances of Hollow Spherical $\text{Li}_4\text{Ti}_5\text{O}_{12}$ for Lithium Ion Batteries

Yingbin Lin, Zhigao Huang

Fujian Provincial Key Laboratory of Quantum Manipulation and New Energy Materials  
Fujian Normal University (Qishan Campus), Minhou District, Fuzhou, Fujian, 350117 China.  
yblin@fjnu.edu.cn

Hollow spherical  $\text{Li}_4\text{Ti}_5\text{O}_{12}$  anode powders were synthesized by spray drying under low vacuum level, followed by the calcination at  $800^\circ\text{C}$  for 12, 16 and 20 h respectively. The structure, morphology, and texture of the as-prepared composites were characterized with XRD, Raman, TG-DTA and SEM techniques. The electrochemical properties of the as-prepared composites were investigated systematically by charge/discharge testing, cyclic voltammograms and AC impedance spectroscopy, respectively. It is found that all as-prepared powders show hollow spherical structure. In comparison, the sample calcined for 16 h exhibited best electrochemical performances. Analysis from the electrochemical measurements revealed that the sample calcined for 16 h had the lowest charge-transfer resistances and highest lithium diffusion rate.

The accumulated spent nuclear fuel (SNF) from current nuclear power plants remains a formidable challenge despite the wide use of nuclear energy. One of the promising solutions is to reduce the spent oxide fuel and recycle it as metal fuel for fast neutron reactors through pyroprocessing. This enables increasing the uranium (U) usage efficiency and decreasing both the radiotoxicity and the amount of radioactive waste generated, thereby increasing the safety and economic efficiency. Pyroprocessing based on molten salt involves the reduction of spent oxide fuel into a metal through an electrolytic reduction process and the recovery of the fuel components by means of an electrorefining process. The actinide metal oxide is reduced to metal in the electrolytic reduction process operated in a  $\text{Li}_2\text{O}$ - $\text{LiCl}$  molten salt medium at 650 °C. Then, the metallic product is used as an anode for the electrorefining process. In the electrorefining process, the actinide metals are electrochemically dissolved and transported to the bulk  $\text{LiCl}$ - $\text{KCl}$ - $\text{UCl}_3$  molten salt at 500 °C, whereas high purity U metal is deposited on a solid cathode. Subsequently, the cathode is changed with a liquid cadmium and the transuranic elements (TRUs) as well as U remaining in the salt are simultaneously deposited onto a liquid cadmium cathode (LCC). In a flow diagram of pyroprocessing in KAERI, an inert anode (graphite) is used instead of actinide metal in LCC electrorefining to increase the recovery of TRUs. To increase the metal recovery of the electrorefining process, multiple electrode pairs have been employed in the electrorefiner [1, 2]. Previously, we reported an anode-liquid cathode module (ALCM) having a compact structure to increase the efficiency of group actinide recovery by adopting multiple modules in an electrolyte bath [3]. The present work aims at investigating the performance of ALCM in molten  $\text{LiCl}$ - $\text{KCl}$ - $\text{UCl}_3$  (3.1 wt.%) -  $\text{NdCl}_3$  (2.6 wt.%) salt and identifying the ratio of U : Nd in the recovered metal product. When current-controlled electrolysis (50  $\text{mA}/\text{cm}^2$ ) was conducted, the passed charge was 0.51 A·hr, which is consistent with 1.4 wt% U/Cd. The cathode potential was maintained as -1.5 to -1.55 V, while the anode potential was 1.8 to 1.9 V, indicating a chlorine gas evolution. After the termination of the electrolysis, the metal deposits (U and Nd) were separated in a Cd distiller and then dissolved in nitric acid for an elemental analysis. The metal recovery efficiency was over 82 % and the U:Nd ratio in the product was determined to be 95:5. This work was supported by a grant from the Nuclear Research & Development Program of NRF funded by the MSIP, Republic of Korea.
